Based on theoretical postulations and empirical factor analysis, five themes have emerged from these dimensions: (1) meaning (e.g., importance, self-identity, value congruency), (2) manageability (e.g., control, likelihood of successful completion, progress), (3) connection (e.g., visibility, importance as viewed by others, support from others), (4) positive affect (e.g., enjoyment, hope, love), and (5) negative affect (e.g., stress, angry, depressed). Positive and negative measures of well-being (e.g., respectively life satisfaction and depression) have been consistently associated with these project themes (Little and Gee, 2007; see also Little, 1989, 2011). People experience more well-being when their projects are more meaningful, manageable, positively connected with others, and associated with more positive affect relative to negative affect.

Ad Hoc Dimensions

In the first publication about the method, Little (1983) stipulated that PPA is designed to be a flexible measurement approach. Thus, standard dimensions should be complemented by dimensions that are pertinent for the specific group of persons studied and their particular eco-setting. These ad hoc dimensions refer to aspects of the individuals and their transactions with their social ecological contexts. For example, researchers have asked participants to appraise their projects in terms of flow (Omodei and Wearing, 1990), organizational support (Little et al., 2007), and supportiveness of neighborhood environments (Sugiyama

and Ward Thompson, 2007). Results from multiple studies suggest that ad hoc dimensions often emerge as key and distinctive predictors of well-being (Little and Gee, 2007). For example, in a sample of Southeast Asian immigrants to Canada, the absence of language difficulties posed by their personal projects was an excellent predictor of well-being (see Little and Gee, 2007).

Once the appraisal module has been completed, person-centered (idiographic) analyses can be performed. Within a single case, it is possible to compute the correlations

between two appraisal dimensions across the person's projects. Alternatively, scores from the appraisal matrix can be averaged across projects in order to provide indices reflecting the global state of the person's project system on each dimension. The mean scores are then used in variable-centered (normative) analyses to study how between-person variation at the level of the project system is associated with variation in other characteristics (e.g., sociodemographic characteristics, personality traits, well-being, etc.). Hierarchical statistical procedures can also be applied to PPA data (e.g., Nurmi et al., 2009) to simultaneously consider both within- and between-persons variation and it is likely that such an analytic strategy will become widely adopted.

Extrapolation of research findings from one level to the other must be made with caution because the results obtained at one level might not be true at the other level, as a particular case of Simpson's paradox. For example, data from Peter's example (Figures 3 and 4) reveal a strong positive correlation ($r = 0.93$) between the dimensions *Responsibility* and *Angry*. In contrast, data from a group of participants ($N = 184$) in research conducted in Little's laboratory, analyzed at the normative level, reveal a modest negative correlation ($r = -0.22$). Interestingly, Peter's means on these dimensions (respectively 8.70 and 2.10 for *Responsibility* and *Angry*) are relatively similar to the group means (8.45 and 1.68). Such diverging and complex results might be of particular interest for a clinical psychologist or a counselor who wants to stimulate discussions with Peter. However, on the whole, examination of individual and normative project space suggests that there is a high degree of isomorphism between idiographic and nomothetic project spaces (see Little, 2000b).

Other Modules: Cross-Impact and Hierarchical Analysis Modules

People are typically engaged in multiple projects, particularly if the focus is on daily pursuits rather than hourly activity, and these projects may facilitate or frustrate each other. The Cross-Impact Matrix of PPA addresses the relationships between projects. One way of assessing this is to ask participants to indicate if the impact is positive or negative, using plus or minus signs. The relationship between two projects is not necessarily reciprocal as shown in Peter's example in Figure 5. He estimates that working on completing his PhD has a strong positive impact on his project to be happy. However, being happy has a null impact on his PhD completion. The projects to lose 15 pounds and have fun with his friends this week-end have negligible effect on other projects. Only the project to adopt a child seems to frustrate more than one of the other

Matrix 3: How do your projects impact *each other*?

Now for each project separately, starting with project 1 on the left, decide whether the project will have (or is having) a positive (+) very positive (++), negative (-) very negative (- -) or neutral impact (0) on the remaining projects (across the top).

Do the same for project 2, 3 etc. all the way to 10, filling in the blocks on both sides of the diagonal.

Remember, evaluating the impact of project 2 on project 3 is not necessarily the same as evaluating the impact of project 3 on project 2. That is why we want you to complete the entire matrix.

projects according to Peter's point of view. In contrast, Peter's project to complete his PhD is the one that affects the most his other projects, and in a positive way. Little (2007, 2011) suggests that human flourishing is contingent upon the sustainable pursuit of core projects. Core projects are operationalized as projects that are more central to the project system, i.e., those which are strongly linked to other projects and which would have the most impact if abandoned (Little, 2007, 2011). Peter's project to complete his PhD satisfies this criterion and is probably crucial to his well-being.

Taking into account the social ecological context in which personal projects are enacted, the Joint Cross-Impact Matrix (optional) aims to explore the impact of a significant other person's projects on the participant's projects. The matrix follows the same logic as the individual Cross-Impact Matrix. Global indices of positive and negative impact can be computed, with greater negative impact indicating more relational difficulties between the two persons (Little and Gee, 2007).

The last PPA module (optional) focuses on the hierarchy of personal projects. This module derives from the conceptualization of personal projects as middle-level units located in a hierarchy between schedulable acts (at the molecular level) and superordinate goals or values (at the molar level). PPA provides a way of studying the linkage between these three levels by an adaptation of a *laddering* technique used in personal construct research. In Why-laddering, individuals are asked *why* they are engaged in each of their projects. To each of these answers they are again asked why they are engaged in them. This iterative process continues until the answer is regarded as an end in itself – a terminal value. How-laddering proceeds in the same way but asks *how* each project is going to be carried out. Again, for each answer the 'how' question is repeated iteratively until a schedulable act is reached. This module has mainly received interest from clinicians. However, research suggests that the personal project hierarchy could be better represented as a lattice than a ladder, with multiple acts accomplished for a single project and multiple reasons while pursuing it (see Little and Gee, 2007).

Figure 6 presents a diagram that exemplifies the hierarchical structure of Peter's projects, starting with his core project of completing his PhD. Peter is completing his PhD for the terminal reason of being happy. In order to complete his PhD, he will engage in a variety of actions, themselves with multiple ramifications: finish his thesis, do a credited internship, complete his data analysis, submit a scholarship application, etc. Although primarily useful as a clinical or counseling tool, the hierarchical analysis has relevance to broader theoretical issues. For example, it is postulated that projects are sustainable to the extent that they are closer to terminal values and therefore high in a sense of meaning. But it is also postulated that projects are sustainable to the extent that they are closer to schedulable acts and therefore high in manageability. This poses the real possibility of a meaning–manageability trade-off in the pursuit of daily projects (Little, 1989, 2011).

SEAbank

The Social Ecological Assessment Databank (SEAbank) integrates data collected since the 1970s in the studies conducted by Little and his students and colleagues in the Social Ecological Research Groups at Carleton, Harvard, and Cambridge universities. Data from 22 studies that took place since 1978 are included in the electronic database and these are updated periodically. This represents more than 12 000 personal projects and 3500 research participants from a diversity of groups and eco-settings. Data in SEAbank comprise project content in a participant's own words, project categorization, appraisals on standard PPA dimensions, sociodemographic variables, personality scores (e.g., Big Five dimensions), and diverse measures of well-being. The aggregation of data from multiple studies over several decades offers a unique opportunity to explore such issues as generational effects in project appraisals across decades and meta-analyses on the relation between personal project appraisals and well-being (see Little and Gee, 2007). The following questions are currently being explored using SEAbank: At the system and project levels, do hedonic (i.e., positive affect) and eudaimonic (i.e., meaning) aspects of personal projects represent distinct constructs as recently debated by researchers in the positive psychology movement? In multilevel modeling, when taking all pertinent variables into account (each project category, characteristics of the project system, personality measures, gender, age), which variables best predict project appraisal? The diversity of SEAbank participants' background also permits the investigation of commonalities and specificities in the pursuit of their personal projects.

Psychometric Findings

Psychometric qualities of PPA have been the object of a detailed examination, using the initial standard dimensions, which were mainly cognitive (Little and Gee, 2007). Test–retest stability (24 h and 2 weeks) proved to be moderate, whether considering all projects or only those that were identified as the same at both measurement times. Stability was higher for dimensions reflecting more stable aspects of personality (e.g., meaning dimensions). Considering that PPA was designed to take into account the fluctuating ecosystemic aspects of project pursuit, this moderate stability is satisfying. Indeed, this suggests a desirable level of sensitivity to change. Concerning internal consistency, a moderate alpha coefficient has been obtained for each appraisal dimension when considering the scores given by participants across their projects (Little et al., 1992). This moderate alpha is expected due to the dynamic nature of the project system. Also concerning reliability, high interrater agreement is generally reached when coding project categories according to domains of activity (Little and Gee, 2007).

The factorial structure of personal project appraisals has varied as new dimensions have been added to the original set, especially those more affective dimensions. Factor analyses performed on data collected with the 17 cognitive and nine affective dimensions support a five-factor structure: meaning, manageability, connection, positive affect, and negative affect (Little, 2011; Little and Gee, 2007). It is noteworthy that the positive and negative affective dimensions are orthogonal. Research has shown independent associations between each of these factors and measures of quality of life and clinical concerns like depression (Little, 2011), adding evidence to PPA construct validity. More details on the psychometric and statistical aspects of PPA research can be found in Little and Gee (2007).

Representative Research

In this section, some research findings will be presented in order to exemplify the variety of studies conducted on personal projects. To organize these findings, the social ecological model of human well-being (Little, 1999) will be used. As shown in **Figure 1**, personal projects constitute the central part of the model. The main relationships between the elements of the model can be summarized as follows. Stable characteristics of the person (box A) and stable contextual features (box B) both influence personal projects (box E). The first emanate from evolutionary and genetic sources, and the second from social scripts, rules, and norms. The third originate from idiosyncratic concerns and values. Dynamic aspects of the person (box C) and the context (box D) also have an impact on personal projects. For example, a biogenic extravert may act as a pseudointrovert for the sake of his/her project. A person's perceived affordances of his/her living environment might influence his/her decision to pursue or not a project. Such environmental perceptions are considered dynamic contextual features because they are more flexible than aspects like macrolevel economic or political conditions, which are more resistant to change. Finally, personal projects contribute to human well-being (box F).

Much of the research that has been conducted on personal projects fits into this model, covering one or more of the arrows in **Figure 1**. Here is a selection of representative research findings for each arrow connected to personal projects in the model.

A ➔ E. Emerging from the field of personality science, personal projects have been examined in relation to personality traits in many studies (e.g., Albuquerque et al., 2013; Little et al., 1992). Considering the Big Five dimensions, openness to experience, conscientiousness, extraversion, and agreeableness have been associated with a positive project appraisal across many PPA dimensions, with conscientiousness having the strongest pattern of correlations (Little et al., 1992). Neuroticism is linked to negative project appraisal (Little et al., 1992). The associations vary depending on the categories of projects: the associations of project appraisal with extraversion and agreeableness were particularly important in the case of interpersonal projects. A recent study using structural equation modeling has demonstrated that personality dimensions, except extraversion, have indirect effects on well-being through their impact on the perception of project efficacy (Albuquerque et al., 2013). However, supporting the relative distinctiveness between personality traits and projects, Salmela-Aro et al. (2012) have shown

that genetic effects contribute to the content of personal projects, over and above genetic influence shared with personality traits. The relationships between character strengths and personal projects have also currently been examined in a study exploring the strengths that people with physical disabilities perceive as most useful to the accomplishment of their projects (Jutras et al., 2012).

B ➔ E. The impact of stable contextual features (i.e., objective environmental characteristics) on project pursuit has received limited attention. As mentioned earlier, a study conducted with SEAbank has focused on generational effects on personal projects, providing insights concerning the eventual influence of societal transformations that have occurred across decades since the development of PPA (see Little and Gee, 2007). The study revealed high levels of stability across decades. Recent results reported in Little and Frost (2013) also exemplify the kind of influence that macrosocial aspects of eco-settings have on personal projects. This study examined the intimacy-related projects of lesbian, gay, and bisexual individuals in comparison with heterosexuals. Although, the projects were rated as equally meaningful by the two groups, the first perceived more macrosocial devaluation (e.g., from media, religious groups, government) and structural barriers (e.g., laws and policies) to their projects. It should be noted that this influence is likely to be reciprocal. By publically pursuing intimacy projects, members of sexual minorities collectively act as change agents in their eco-settings: in the long term, they might have a positive impact on the macrosocial devaluation and barriers that impede their intimacy projects (Little and Frost, 2013).

C ➔ E. Dynamic person features have received less empirical attention than stable person features. At the theoretical level, Little's free trait theory (Little, 2000a; Little and Joseph, 2007) postulates that individuals may act out of character when pursuing some of their core personal projects. A biologically introverted person, for example, may find that the successful pursuit of a professional aspiration may entail acting as a (pseudo)extravert. However, such acting out of character, while advancing a person's projects, might have a toll on physical and mental well-being in the long term. The theory proposes that the availability of *restorative niches* where people can freely act in concordance with their first nature can mitigate the negative consequences of acting out of character. Empirical evidence providing initial support for free trait theory has been reported by Little and Joseph (2007).

D ➔ E. Contrary to the limited knowledge on stable (or objective) contextual features, many studies in environmental psychology and urban planning demonstrate that people's perception of their proximal environment plays an important role in the pursuit of their personal projects. For instance, Wallenius (2004) has shown that noise annoyance in the dwelling (due to traffic outside) is correlated with the perception of more stressful projects. In another study (Wallenius, 1999), adult participants from Finland rated the extent to which the places where they pursue their personal projects (mainly home, workplace, and sports facilities) were supportive of their projects. The higher the degree of supportiveness, the higher the level of expected accomplishment. Roe and Aspinall (2012) have shown that, in comparison with local environment, faraway and citywide settings are niches where adolescents from Scotland experience more positive affect and less negative affect while pursuing their projects. Sugiyama and Ward Thompson (2007) have examined the perceived supportiveness of neighborhood environments for older people's outdoor activity projects. In the same vein, in a study conducted in assisted living facilities for people with severe physical disabilities, Jutras et al. (2012) have explored the qualitative perceptions of residents and staff about social and environmental support to residents' projects.

E ➔ F. As stated earlier, well-being is promoted by projects that are more meaningful, manageable, positively connected with others, and that are associated with more positive affect and less negative affect (Little, 1989, 2011). Various aspects of well-being have been examined: hedonic (e.g., satisfaction with life, Palys and Little, 1983), eudaimonic (e.g., purpose in life, McGregor and Little, 1998), and physical well-being (e.g., diabetes metabolic control, Karoly and Bay, 1990). Salmela-Aro and her colleagues have developed a major research program concerning the role of personal projects in adjustment to critical life transitions. For example, longitudinal data suggest that it is beneficial for women to actively adjust their projects during the transition to parenthood: after childbirth, an increase in family projects was associated with a diminution of depressive symptoms (Salmela-Aro, 2012). Highlighting the tractability of personal projects for well-being promotion, Salmela-Aro (2012) has shown that a group intervention can be effective in increasing family projects and have a positive impact for nulliparous women with a severe fear of childbirth.

Conclusion

The study of personal projects has been steadily growing since the introduction of PPA methodology in 1983. It offers an alternative to trait and narrative theories of personality, a methodology that meets the twin challenges of humane and rigorous assessment and a wide-ranging research program that focuses on the diverse ways in which the pursuit of projects enhances well-being. Its adoption in diverse fields of basic and applied research continues to stimulate interdisciplinary research on those forces, both internal and external, that help explain and enhance the quality of lives.

Abstract

Personality is viewed as a self-regulatory system and adaptive behaviors as modes of person–environment interactions that maximize individuals' well-being and development. Over the course of life, people acquire competencies, knowledge about themselves and the social world, and standards for evaluating the worth of own actions. Self-reflective and self-directive processes enable individuals to pursue optimal adjustment by taking advantage of environmental opportunities and selecting activities which optimize the actualization of their potentials.

Personality is the psychological system that mediates the relationship of the individual with the environment in the service of adaptation. It is the complexity of structures, processes and patterns of affect, cognition and behavior that we call 'personality' that conveys to others the sense of unity and distinctiveness that distinguishes individuals from one another and that grants to each individual a sense of identity, of wholeness, and uniqueness. Because the term encompasses a great variety of phenomena, it is not surprising that different ideas appear in various combinations in the traditional and common usage of the word personality: human being, person, the quality of being a person, the quality or fact of being a particular person, patterns of habits and qualities of any individual as expressed through physical and mental activities, the sum of such properties as impressing or likely to impress others, and what makes an individual conspicuously different from others. Nor is it surprising that, given the complex nature of personality, different assumptions, foci, and strategies of research have marked the study of personality since the beginning of the discipline (Allport, 1937; Murray, 1938; Stagner, 1937; Stern, 1935). The resolution of these different definitions and assumptions has considerable implications for the conceptualization and study of adaptation and adaptive behaviors.

Common Assumptions Regarding Personality

Before outlining these different assumptions, let us first consider some areas of commonality in the contemporary field. Most investigators in personality psychology share an 'interactionist view.' In other words, they view personality as an open system that develops and functions through continuous and reciprocal interactions with the environment (Bandura, 1986; Hettema, 1979; Magnusson and Stattin, 1998). Personality, then, refers to a complexity of psychological structures and processes that operate in concert in these person–situation interactions. The personality system underlies the distinctive patterns of affect, cognition, and behavior that foster coherence in individual conduct and experience over time and across settings. Molar psychological mechanisms, such as the goals, beliefs, and skills through which individuals regulate their experiences and actions, result from the synergism of underlying biological and psychological subsystems. Multiple biological systems, cognitive and affective structures, behavior, and the environment all operate as interacting determinants of what personality is at any moment within a network of reciprocal causation. The relative influence of one or another personality determinant varies in different individuals, and across activities and circumstances. Individual development and functioning are processes of continuous restructuring of the whole system and its subsystems within the boundaries set by biological and social constraints (Caprara and Cervone, 2000).

Competing Arguments Regarding Personality

Despite the widespread adherence to an interactionist viewpoint, continuing debates in the field attest to the fact that many fundamental issues are still pending, with different investigators adhering to different theoretical and metatheoretical principles and assigning different importance to nature, nurture, or the individual in the shaping of their personalities (Cervone, 1991). Throughout much of its history, personality psychology has been concerned with individual differences in observable variations in styles of behavior, affect, and cognition. The variations have been organized according to, and traced back to, simple systems of dispositional constructs.

Dispositional constructs are designed to encompass the variety of phenotypic expressions of individuality and to capture the consistent individual differences that are observed. Trait constructs have been posited to account for stable patterns of experience and action that people exhibit, and that distinguish them from one another. As different traits are differentially relevant to different settings and their expression is differentially sensitive to social contexts, different traits attest to the consistency of personality in various degrees depending upon their generalizability (across individuals), pervasiveness (across situations), and stability (across time). This has led dispositional theorists to conceptualize personality as a hierarchical organization and to focus on high-level traits (e.g., extroversion) that organize lower level tendencies (e.g., sociability) which, in turn, supervise lower level behavioral habits (e.g., talkativeness) (Eysenck, 1970).

In the past, alternative taxonomies have been in conflict with each other. However significant consensus recently has been reached on the importance of five factors (so-called Big

 http://dx.doi.org/10.1016/B978-0-08-097086-8.26045-5

Five) that are obtained robustly: extroversion, agreeableness, conscientiousness, emotional stability, and openness to experience. This five-factor model has become a point of convergence between the psycholexical tradition, mostly concerned with personality description (Goldberg, 1993), and the tradition, mostly concerned with the identification of the primary structures of personality (McCrae and Costa, 1996).

Significant differences are found among five-factors investigators, who may disagree on the exact nature and conceptual status of the trait variables (see Wiggins, 1996). However, far more profound differences separate those who view traits as the ultimate determinants of personality from those who conclude that clustering descriptors related to habitual behaviors (as resulting from factor analysis) cannot lead too far in understanding either the regularities that explain personality functioning or the uniqueness which distinguishes persons from one another (Bandura, 1999). The issue in contention is not whether people have personal dispositions, nor their determinative role in personality functioning, but rather how dispositions are conceptualized and operationalized. Dispositions may correspond to habitual styles of behavior rooted in genotypes, or to self-regulatory structures (as internal standards, aspirations and goals, and efficacy beliefs) resulting from the organization of affect, cognition, and behavior which emerges over the course of life.

In conceiving of personality as a hierarchical architecture in which basic traits are at the origins of any other individual disposition or behavior, most convinced advocates of traits as genotypes of personality derive their arguments from genetic, longitudinal, and cross-cultural studies. Genetic studies have found a consistent component of heritability for each of the Big Five (Lohelin, 1992), longitudinal studies have shown a significant stability of the same traits over the life span (Costa and McCrae, 1997), and cross-cultural studies have shown that the multiple descriptors used to describe personality in different cultures can be traced back to few common dimensions broadly overlapping with the Big Five (De Raad, 1998). The trait psychologist converges with the evolutionary psychologist in viewing adaptation as largely predetermined by the basic dispositional equipment of the species selected through generations. According to this view, adaptive behaviors (in mating, fighting, solving problems, and coping with adversities) largely reflect the influence of evolved mechanisms whose nature and functioning has been determined over the eons through processes of natural selection (Buss, 1997).

In contrast, in conceiving of personality as an open, dynamic, unifying and integrating system, social cognitive and motivational theorists (Cervone and Shoda, 1999) point to the emerging properties of the mind and focus on the processes and mechanisms conducive to knowledge structures which enable personality to function as a proactive self-regulatory system. Thus, they contest the generalizability to individuals of correlational findings derived from studying populations, and thus leaving large portions of variability unexplained. Rather, they focus on the construction of personality as an integrative and coherent system as it takes place over the course of life, on the processes that enable the system to function proactively with the environment and on the structures that orchestrate these processes. Ultimately they emphasize the flow of reciprocal determination among biological, psychological, and social factors which sustain the whole construction, and from which the agentic properties of personality derive. In this view of personality, 'adaptation' is eminently relational and contextual. Adaptive behaviors are not ascribed to any preformed, endogenous dispositions, but to psychological systems which themselves develop through dynamic interactions with the social environment. These systems enable the person to cope in a flexible, innovative manner with the diverse challenges of life.

Personality as a Self-Regulatory System

Personality can be viewed as both a construction and an agentic system. Over time, people gradually construct a sense of self through their interactions with the social world. People's capacity for forethought, performance control, and self-reflection contributes to their ability to regulate their own experiences and actions. Self-regulatory capacities enable people to contribute proactively to the course of their development. Personality, then, reveals itself as a construction endowed with agentic properties. These properties enable people to exert a broad influence on their environment and their own psychological and physical selves (Caprara and Cervone, 2000).

Agentic personality functioning involves a number of distinct processes. People select the environments they encounter and thereby create opportunities for themselves, guide their behavior purposively, appraise their circumstances, and chose levels of mental and physical challenge that match their perceived capabilities. Person–situation transactions underscore the fact that personality functioning is not reactive but proactive. Individuals do not only react to the environments, but actively contribute to their transformation and creation. Individuals' distinctive ways of functioning reflect more than the unfolding of a genetic blueprint or the interactions which have taken place between the organism and the environment over the course of development. They also reflect individuals' active role in shaping their own personality.

Thus, one should look at adaptation as a dynamic, proactive process. People do not 'adapt' merely by altering themselves to fit environmental constraints and pressures. They select and transform environments in order to actualize their full potentials and maximize their own well-being. Adaptation relies more on individuals' capacities to devise strategies and to implement tactics able to match successfully the requirements and affordances of multiple situations, than on the fixed pattern of responses. The capacity to expand knowledge of oneselves and of situations is no less important than the capacity to master such knowledge with the flexibility that is required by the variety and continuous change of person–situation transactions.

Over the course of life, people acquire competencies, knowledge about themselves and the social world, and standards for evaluating the worth of own actions. Self-reflective and self-directive processes enable individuals to meet environmental opportunities and constraints as well as to maintain personally valued courses of action in the relative absence of tangible rewards or social support. While people show a striking ability to adapt their behavior to physical,

interpersonal, and social circumstances, and also to select and create the circumstances that best fit with their purposes and abilities, successful adjustment across the life span corresponds to the best allocation of personal and social resources within the set of temporally bound opportunities and constraints.

Adaptive strategies include the realistic adjustment of personal aspirations and goals in accordance with accessible resources and opportunities. This may lead either to develop capacities that allow to alter one's social and physical environment, and to modify one's life views, habits, and internal states. Thus selection, optimization, and compensation have been regarded as main strategies which attest the property of personality to capitalize upon experience in the achievement of higher levels of functioning and well-being. People must select life goals, activities, and pathways that are manageable; they must optimize the allocation of internal and external resources that are made available to them; they must develop strategies to compensate for lacks or losses of goal relevant means (Baltes, 1997; Heckausen and Schultz, 1998).

As people are causal agents who actively contribute to the course of their life in selecting and transforming the environment they encounters, adaptive behaviors are those behaviors that promote the conditions for the full expression of individual capacities and potentials. As individuals' course of life is closely interdependent with the course of life of others, ultimately adaptive behaviors are those behaviors that serve for both the betterment of individual and collective welfare.

Among behaviors fostering successful adaptation, many findings attest to the positive influence of altruistic and prosocial behaviors such as sharing, donating, caring, comforting, and helping (Eisenberg et al., 2006; Penner et al., 2005). Findings from developmental research show that prosocial behavior is positively correlated with well adjustment in children and adolescents while contributing to their accomplishments in social and academic domains (Caprara et al., 2000). The positive impact of prosocial behaviors extends over the entire life span, serving as protective factors that foster self-acceptance, rewarding relationships with others, and life satisfactions, while contrasting antisocial behaviors (Caprara and Steca, 2007; Midlarsky, 1991).

Among knowledge structures fostering successful adaptation across domains of functioning a vast body of research has documented the unique contribution of beliefs of personal efficacy beyond dispositions and skills. Beliefs of personal efficacy influence level of aspirations and goals, what self-regulative standards people adopt, how much efforts they invest in their endeavors, and how resilient they are to adversity (Bandura, 1997). While self-efficacy can be properly developed by proper interventions aimed to strengthen people capacities to reflect and to capitalize upon their experiences, agentic self-beliefs in the domain of affect and interpersonal relations may represent fundamental psychological mediators and moderators that significantly contribute to turn largely inherited tendencies and predispositions into proper views, feelings, goals, and performances (Bandura et al., 2003; Caprara et al., 2010).

In viewing adaptation as a dynamic process that engages the entire personality, future research should address its multiple expressions and structures, how they develop and operate in concert and within their continuous and reciprocal interactions with the environment over the course of life. In particular, it should focus on mechanism and experiences that can strengthen people's capacity to adapt to a rapidly changing world. To this aim, theories and findings are mostly needed to identify the strategies more suitable to promote individual development by enabling people to make choices and to engage in pursuits that mostly serve their growth, health, and well-being.

Personality and Creativity

Abstract

Personality plays an important role in the creative process. The search for the 'creative personality' has a long history, and psychologists have converged on the personality dimension of Openness/Intellect as the most important trait predictor of creative achievement. High levels of Openness/Intellect are associated with an increased tendency toward cognitive exploration, supported by divergent thinking, implicit learning, working memory, and decreased latent inhibition. Collectively, variation in these cognitive processes helps to explain the link between personality and creativity.

Creativity is commonly defined as the generation of mental products (e.g., ideas, mathematical formulas, music, visual art, behaviors, technological innovations, etc.) that are both novel and contextually valuable (Runco, 2004; Sternberg and Lubart, 1999). Creative individuals are those who demonstrate an aptitude for generating such creative products. The study of the 'creative personality' has a long scientific history, with researchers attempting to identify the key psychological characteristics that differentiate highly creative individuals from their less creative counterparts.

History of Research on Creativity and Personality

The scientific study of the creative personality began in late-nineteenth century England with Francis Galton's attempts to understand the heritability of genius. Galton, a cousin of Charles Darwin, observed that prominent families tended to produce a large number of eminent individuals, suggesting to him that intellectual and creative abilities were directly inherited from one's parents and ancestors (Galton, 1869). Galton argued that creative individuals were distinguished by their greater intellectual capacity, which he thought was dependent upon underlying biological differences. No clear differentiation between creativity and intelligence was made at the time, as both were considered to be aspects of the broader dimension of 'genius' or 'eminence.'

Lewis Terman continued Galton's research tradition in America during the 1920s. Like Galton, Terman believed that creative genius was driven by biological factors that produced intellectual superiority. Superior intelligence was thus regarded as the primary factor in predicting creative achievement. Terman tested this hypothesis with a longitudinal study of 1300 intellectually gifted children, all of whom were identified as high scorers on one of the first modern IQ tests, the Stanford–Binet Intelligence Scales (Terman, 1925). As the study progressed, however, Terman observed that only a small fraction of the sample of intellectually gifted children ended up producing significant creative accomplishments as adults (Terman and Oden, 1959). Terman concluded that creative achievement must depend on factors beyond intelligence.

In his 1950 presidential address to the American Psychological Association, J.P. Guilford argued that the study of creativity had been largely neglected by psychologists but was of critical importance (Guilford, 1950). Recognizing that intelligence tests did not account for differences in creative achievement, Guilford argued that a broader range of personality characteristics needed to be considered in order to identify creative individuals. He also suggested that creativity is related to 'divergent thinking,' a pattern of thought in which multiple alternative possibilities are generated, in contrast to 'convergent thinking,' which attempts to identify a single correct solution to a problem (Guilford, 1967). Guilford's research helped to advance the psychometric assessment of creativity as distinct from what is captured by traditional intelligence tests.

Although the psychometric assessment of creativity did not fully emerge prior to Guilford's work, creativity was still regarded as an important process in many theories of personality function. Sigmund Freud believed that creativity involved the sublimation of repressed sexual desires into products of the imagination (Freud, 1908). Carl Jung argued that creativity is driven by powerful unconscious forces that can overwhelm the conscious will of the creative artist who experiences them (Jung, 1933). Alfred Adler regarded creativity as central to an individual's ability to take control of his or her life and transform it for the better (Adler, 1927). Otto Rank viewed creativity as an adaptive process of 'unlearning' socially prescribed beliefs and behavioral patterns, with neurosis reflecting the failure to adapt creatively to life (Rank, 1932). George Kelly suggested that creativity involves the temporary loosening of one's conceptual system, which is then reformed around a novel idea that seems promising (Kelly, 1955). Abraham Maslow regarded creativity as a central component of healthy psychological development and personal growth, naturally emerging from a self-actualizing individual's engagement with the world (Maslow, 1962). Carl Rogers also regarded creativity as a natural human process, emphasizing that it is disrupted when the individual feels threatened, flourishing only under conditions of psychological safety (Rogers, 1961). B.F. Skinner, meanwhile, attributed creativity to the accidental 'mutation' of previously learned behavioral patterns, which are only preserved if they are reinforced by the environment (Skinner, 1970).

Since Guilford's call to scientific action, a large number of personality psychologists have examined the character traits associated with creative achievement, both by examining

creativity in the normal population and by studying the personalities of highly eminent creative people. Some of the personality traits that are most commonly associated with creativity include greater aesthetic sensitivity, broad interests, attraction to complexity, independence of judgment, autonomy and self-direction, tolerance of ambiguity, and a clear sense of one's self as 'creative' (Barron and Harrington, 1981). Many of these characteristics are captured in the 'creative personality scale,' which was designed to assess the personality traits that most clearly distinguish creative individuals from less creative ones (Gough, 1979).

Openness/Intellect and the Five-Factor Model of Personality

Although researchers in the 1950s, 1960s, and 1970s identified numerous personality traits that were associated with creativity, integrating these findings into a coherent framework proved to be difficult. In particular, the diversity of personality taxonomies and scales used by different investigators resulted in a proliferation of overlapping trait constructs with unclear boundaries. Beginning in the late 1980s, however, the five-factor model of personality emerged as an integrative taxonomy for categorizing human personality traits (Digman, 1990). According to this framework, personality varies along five broad trait dimensions: Extraversion, Agreeableness, Conscientiousness, Neuroticism, and Openness/Intellect (Goldberg, 1990). Studies employing the five-factor model have consistently associated greater creative abilities with higher scores on the Openness/Intellect trait dimension, using both self- and peer-rated assessments of personality (McCrae, 1987). While other traits, including high Extraversion and low Agreeableness, have also been related to creative accomplishments, these effects tend to disappear when statistically controlling for Openness/Intellect levels (e.g., King et al., 1996).

As a personality dimension, Openness/Intellect describes the extent to which an individual is prone to aesthetic absorption and cognitive exploration (DeYoung et al., 2005). The broad trait domain is comprised of the two lower-order traits of 'Openness,' which reflects aesthetic sensitivity and imaginative tendencies, and 'Intellect,' which reflects intellectual engagement and interest in abstract ideas (DeYoung et al., 2007). A strong biological basis exists for Openness/Intellect, with approximately 61% of the variance in this trait being driven by genetic factors (Jang et al., 1996). Genetic variation in the mesocortical dopamine system, which supports cognitive exploration and flexibility, has been identified as contributing to an individual's standing on this trait dimension (DeYoung et al., 2011).

Cognitive Processes Linking Openness/Intellect with Creativity

Openness/Intellect has been associated with a number of cognitive processes that appear to support its relationship with enhanced creativity, including decreased latent inhibition and superior divergent thinking, implicit learning, and working memory performance.

Decreased Latent Inhibition

Individuals with higher levels of Openness/Intellect have been observed to display decreased latent inhibition (Peterson and Carson, 2000). Latent inhibition describes the cognitive process by which stimuli with no apparent motivational relevance are marked as insignificant and not worthy of further attention. Those with high levels of latent inhibition have difficulty learning new associations with previously encountered objects, relying instead upon existing memories derived from previous experience. Decreased latent inhibition, on the other hand, is associated with the ability to examine familiar objects and ideas as if they were being encountered for the first time. This ability to reexamine and transform familiar meanings into novel patterns is in turn associated with higher levels of creative achievement (Carson et al., 2003).

Divergent Thinking

Openness/Intellect is also the best personality predictor of divergent thinking (McCrae, 1987; Silvia et al., 2009). Since Guilford's seminal work on the topic, divergent thinking has been considered to be one of the core cognitive processes that support creative idea generation because it involves the proliferation of creative possibilities. Tests of divergent thinking, such as asking people to think of as many unusual uses for a familiar object as they can (Torrance, 1966), are able to predict a variety of real-world creative outcomes (Runco, 1991). Openness/Intellect appears to support the generation of novel possibilities and cognitive associations.

Implicit Learning

The subtrait of Openness has been associated with the facilitation of implicit pattern learning (Kaufman et al., 2010). Although we learn many things using conscious, or explicit, processing, we also learn a great deal implicitly, or without conscious awareness (Reber, 1989). Implicit learning has long been theorized to play an important role in the creative process. In particular, it has been argued that creative ideas begin as implicit or unconscious representations, which need to be explicitly articulated in a symbolic form during the creative process (Policastro, 1995). Unconscious processing has indeed been identified as an important aspect of creativity, due to its predominantly divergent and associative nature (Dijksterhuis and Meurs, 2006). Implicit learning appears to facilitate the generation of creative insights during the so-called 'incubation' phase of creative problem-solving, when no conscious efforts are being made toward a solution (Dorfman et al., 1996). Higher levels of Openness thus appear to support creativity through the facilitation of implicit learning and intuitive information processing (McCrae, 1993). This heightened ability to learn implicit patterns may also facilitate the use of analogical reasoning, which supports creative idea generation (Holyoak and Thagard, 1995).

Working Memory

The subtrait of Intellect is the only personality trait that shows consistent relationships with standard measures of

intelligence, and it has been uniquely associated with brain activity in regions that support working memory (DeYoung et al., 2009). Working memory capacity describes the amount of information that can be simultaneously apprehended by an individual, and reflects one of the core components of intelligence. Working memory capacity varies tremendously from one person to the next, with some people being able to attend to and process a much larger amount of information (Engle et al., 1999). Being able to process more information simultaneously is likely to allow a broader range of creative idea combinations to emerge into consciousness (Campbell, 1960).

It should be pointed out that although an individual's Openness/Intellect scores can predict creative achievement beyond the effects of intelligence alone, there is still a significant positive relationship between intellectual ability and creative achievement. According to the threshold hypothesis, however, the relationship between intelligence and creativity tends to drop substantially once a critical level of intelligence is reached (an IQ of approximately 120; Batey and Furnham, 2006).

Collectively, the psychological processes associated with Openness/Intellect reflect the tendency to explore and revise perceptual patterns and cognitive models of the world (DeYoung, 2014). The heightened 'permeability of consciousness' associated with this personality dimension appears to play a critical role in facilitating the creative process (McCrae, 1994).

Changes in Openness/Intellect over Time

Although Openness/Intellect has a large genetic component, it can also change over time as a result of experience. On average, scores on this trait dimension tend to rise sharply during adolescence and then begin to decline during old age (Roberts et al., 2006). It may be possible to preserve levels of Openness/Intellect into old age, however, using cognitive exercise. An intervention with older adults found that a 16-week inductive reasoning training program, which included weekly Sudoku and crossword puzzles, resulted in a significant increase in Openness/Intellect as compared to a wait-list control group (Jackson et al., 2012). Other life events, such as marriage, appear to hasten the age-related declines in this trait (Specht et al., 2011). Pharmacological interventions also appear to have an influence, with a single high dose of psilocybin producing spiritual experiences that led to increased Openness/Intellect scores being observed a full year later (MacLean et al., 2011).

It is also worth noting that modern personality theories recognize that there are substantial within-person fluctuations in personality characteristics from one situation to the next. What this suggests is that a relatively 'creative person' will not necessarily be creative at all times. A person's overall score on a standard personality test in fact represents his or her 'average' standing on a given trait dimension, which can vary depending upon the situational context (Fleeson and Gallagher, 2009). An individual's degree of Openness/Intellect, and thus his or her 'creative potential,' can therefore change substantially from one situation to another.

Creativity and Psychopathology

Openness/Intellect is also relevant for understanding the fact that creativity has long been associated with psychopathology in the popular imagination, with a thin line separating madness from genius. Indeed, Hans Eysenck proposed that creativity is facilitated by subclinical levels of psychotic tendencies (Eysenck, 1993). In particular, he argued that although schizophrenia has often been regarded as a categorical disorder, it should more appropriately be regarded from a dimensional perspective as a spectrum of cognitive and emotional patterns that vary throughout the entire population. Recent work has confirmed that the positive symptoms of schizotypy are associated with extremely high levels of the personality trait of Openness (Edmundson et al., 2011; Piedmont et al., 2009). Excessive Openness (but not Intellect) appears to be related to an increased tendency toward magical beliefs and unusual perceptual experiences (DeYoung et al., 2012). While the ability to detect and develop novel sensory and ideational patterns is associated with enhanced creativity, it can also result in delusional thinking and a loosened grip on social reality. The extent to which Openness is associated with creativity rather than schizotypy may depend upon the individual's ability to integrate the ongoing flow of novel cognitive and sensory patterns within a coherent worldview. High levels of intelligence are in fact a protective factor against schizotypal diagnosis (David et al., 1997), suggesting that strong convergent thinking abilities are needed to 'reign in' the tendencies toward divergent thinking that are associated with very high levels of Openness. Traits related to schizotypy do not appear to predict creative success beyond the effects of Openness and Intelligence (Miller and Tal, 2007), suggesting that any of the creative benefits of schizotypy are mediated through the same processes as those associated with Openness/Intellect.

Personality and Domain-Specific Creativity

Although Openness/Intellect is associated with creativity across a variety of domains, the importance of other personality traits appears to vary depending upon the specific domain of creative endeavor. A meta-analysis that examined the personality characteristics associated with scientific and artistic creativity found that higher levels of Openness/Intellect predicted creativity in both domains (Feist, 1998). Creative scientists, however, had substantially higher levels of Conscientiousness (the tendency to be organized and industrious), whereas creative artists displayed lower levels of Emotional Stability (the tendency to experience negative emotion). A recent study examining how scientific and artistic creativity map onto the lower-order personality traits within the five-factor model found that while higher levels of Openness were associated with creativity in artistic domains, higher levels of Intellect were associated with creativity in scientific domains (Kaufman, 2009).

An important point to take from the research on personality and creativity is that there are in fact many different varieties of 'creative personality.' While Openness/Intellect appears to be the strongest and most reliable trait predictor of creativity across different domains, creative success may also require other traits depending upon the specific field (Baer, 1998). Creative individuals are thus likely to be united by their high

levels of Openness/Intellect, but may vary broadly in terms of their other personality characteristics.

Personality and Crime

Abstract

Personality traits are persisting underlying tendencies to behave in particular ways in particular situations. Temperament is the childhood equivalent of personality, and a difficult, undercontrolled temperament in infancy predicts later offending. The most crucial personality trait that predicts offending is impulsiveness, which may reflect deficits in the executive functions of the brain. Low empathy is probably related to offending, but the evidence is less convincing. Psychopathic personality (a cold, callous personality, including low empathy, low guilt, and low remorse) is more clearly correlated with offending. The Eysenck theory links extraversion, neuroticism, and psychoticism to offending, but analyses of Eysenck's personality inventories show that the most significant relationships reflect items measuring impulsiveness. Currently, the most widely accepted personality system is the five-factor model or 'Big Five' personality dimensions. Of these, agreeableness and conscientiousness are most strongly correlated (negatively) with offending. More research is needed on the theoretical linkages between personality constructs and offending and on their biological bases. Longitudinal studies are especially needed in which changes in personality constructs are related to changes in offending. The main policy implication of research on personality and crime is that it is desirable to implement cognitive-behavioral skills training techniques to try to counteract high impulsiveness and low empathy.

It is a basic assumption of psychology that behavior arises out of the interaction between the individual and the environment. Studies have shown that behavior is generally consistent over time or, more accurately, the relative ordering of individuals is remarkably consistent over time. It is hypothesized that this behavioral consistency depends primarily on the persistence of underlying tendencies to behave in particular ways in particular situations. These tendencies are termed personality traits, such as impulsiveness, sensation seeking, assertiveness, modesty, and dutifulness. Personality dimensions, such as extraversion, are clusters of personality traits that are typically found to be associated with one another (e.g., impulsiveness and sensation seeking). Roberts and Del Vecchio (2000) found that average test–retest correlations increased from .31 in childhood to .54 in the college years and .74 in adulthood (for an average time interval of 7 years).

Many constructs that are assumed to underlie behavior are not included under the heading of personality. This is true, for example, of intelligence and moral reasoning, and of cognitive processes such as thinking, reasoning, and decision making. However, the boundaries between personality and all of these constructs are not well defined. For example, it has been suggested that neuropsychological deficits in the executive functions of the brain (e.g., reasoning, planning, sustaining attention, and concentration) can cause both low IQ and high impulsiveness (Moffitt, 1990). This article will focus on topics conventionally included under the heading of personality; there is not space here to discuss underlying biological processes in any detail (see e.g., Beaver and Walsh, 2010).

The most common types of offending studied are burglary, theft, violence, vandalism, fraud, and drug offenses. Since crimes are a subset of antisocial acts, any potential to commit crime is probably part of a broader potential to commit antisocial acts, but the focus here is on crime. The focus is also on normal personality, and as far as possible discussions of related psychiatric conditions such as antisocial personality disorder, psychopathy, and attention deficit-hyperactivity disorder are avoided. However, the boundary between normal and pathological behavior is not always clear, depending on judgments about the extent to which normal functioning has been impaired. There will also be some discussion of psychopathic personality.

In understanding the potentially causal relationship between personality and crime, tautological statements should be avoided. Any construct that is presumed to cause crime should be measuring something different from crime. Thus, it is useful to investigate the extent to which low empathy causes crime and less useful to investigate the extent to which high aggressiveness causes violent crime because both are probably behavioral manifestations of the same persisting underlying theoretical construct. Early research using the psychopathic deviate scale of the Minnesota Multiphasic Personality Inventory and the socialization scale of the California Psychological Inventory was essentially tautological in showing that antisocial behavior was correlated with offending (Wilson and Herrnstein, 1985: pp. 186–194).

A bewildering number of personality traits and dimensions have been postulated, measured, and related to offending. In some cases, different terms are probably used to describe the same underlying construct. Only the most important topics can be reviewed here: temperament, impulsiveness, empathy, the Eysenck theory, and the 'Big Five' personality dimensions.

Temperament

Temperament is basically the early childhood equivalent of personality, although there is more emphasis in the temperament literature on constitutional predisposition and genetic and biological factors that influence temperament. The modern study of child temperament began with the New York Longitudinal Study of Chess and Thomas (1984). Children in their first 5 years of life were rated on temperamental dimensions by their parents, and these dimensions were combined into

 http://dx.doi.org/10.1016/B978-0-08-097086-8.45032-4

three broad categories of easy, difficult, and 'slow to warm up' temperament. Having a difficult temperament at ages 3–4 years (frequent irritability, low amenability and adaptability, irregular habits) predicted poor adult psychiatric adjustment at ages 17–24.

Remarkably, Bates (1989) found that mothers' ratings of difficult temperament as early as age 6 months (defined primarily as frequent, intense expressions of negative emotions), predicted mothers' ratings of child conduct problems between the ages of 3 and 6 years. Similar results were obtained in the Australian Temperament Project, which found that children who were rated as irritable, not amenable, or showing behavior problems at ages 4–8 months tended to be rated as aggressive at ages 7–8 years (Sanson et al., 1993). When information at each age comes from the same source it is possible that the continuity lies in the rater, rather than the child. However, in a sample of 103 children followed up from age 2 to age 17, Guerin et al. (2003) found that difficult temperament in infancy, rated by mothers, predicted a greater frequency of attention problems, aggressive problems, and thinking problems in the elementary school years, as reported by teachers.

Other researchers have investigated more specific dimensions of temperament than the rather vague 'difficult temperament.' For example, Kagan et al. (1988) in Boston classified children as inhibited (shy or fearful) or uninhibited at age 21 months on the basis of their observed reactions to a strange situation, and concluded that about 10–20% of children were inhibited, while about 30–40% were uninhibited. They found that children were significantly stable on this classification up to age 7 years. Furthermore, the uninhibited children at age 21 months significantly tended to be identified as aggressive at age 13 years, according to self and parent reports (Schwartz et al., 1996).

There are several systems for classifying childhood temperament. Evans and Rothbart (2007) identified three important dimensions: (1) effortful control (including planning ahead and the suppression of inappropriate responses), which was related to the 'Big Five' dimension of conscientiousness in adulthood (see later); (2) negative affect (including frustration, fear, and sadness), which was related to the 'Big Five' dimension of neuroticism; and (3) extraversion (including impulsiveness and low shyness), which was related to the 'Big Five' dimension of extraversion. Lahey et al. (2006) also identified three important dimensions (low prosociality, negative emotionality, and high daring) and showed that all three, measured at age 7, predicted delinquency up to age 17 in the Pittsburgh Youth Study, which is a prospective longitudinal survey of over 1500 Pittsburgh boys.

The most important results on the link between childhood temperament and later offending have been obtained in the Dunedin longitudinal study in New Zealand, which has followed up over 1000 children from age 3 years into their thirties. Temperament at age 3 years was rated by observing the child's behavior during a testing session involving cognitive and motor tasks. The most important dimension of temperament was being undercontrolled (restless, impulsive, with poor attention), which predicted aggression, self-reported delinquency, and convictions at ages 18–21 years and problem gambling at age 32 years (Caspi, 2000; Slutske et al., 2012).

Impulsiveness

The most important study of childhood temperament in relation to later offending essentially identified impulsiveness as the key dimension, and it is generally true that impulsiveness is the most crucial personality dimension that predicts offending. There are a large number of constructs that refer to a poor ability to control behavior. These include low self-control, hyperactivity, inattention, a poor ability to delay gratification, short time horizons, risk taking, sensation seeking, and not considering consequences before acting. There are differences among the specific definitions of many of these terms, but all these variables (variously measured) are consistently related to offending (Ellis and Walsh, 2000: p. 217). Impulsiveness is genetically influenced and relatively stable over time (Niv et al., 2012).

High impulsiveness might contribute to an increased likelihood of offending either directly or indirectly. By the direct pathway, impulsiveness would have a fundamental impact on the way in which an individual would act in any given situation. With less time and cognitive energy available for contemplation of potential responses, an impulsive individual would, on balance, select the option that provides the most immediate perceived benefit. Numerous researchers and theorists have detailed how criminal offending tends to satisfy immediate urges at the risk of later, uncertain, and possibly negative consequences (e.g., Farrington and Welsh, 2007: p. 52).

Other researchers have suggested that high impulsiveness may contribute to an increased likelihood of offending indirectly through a person–environment interaction (e.g., Neumann et al., 2010). Impulsiveness may have different effects in different families and neighborhoods. Also, an impulsive child may prove a challenge to even the most conscientious parent, over time eliciting poor parenting, which is in itself an established risk factor for later offending. Thus, there may be child effects on parenting that lead to offending. Similarly, impulsiveness may lead to offending by reducing the likelihood of school success. Typically, formal education is delivered in a restrictive environment that might prove very difficult for children who are impulsive. Thus, impulsiveness may lead to low achievement, which in turn leads to offending. Children who have low school achievement are more likely to drop out of school and more likely to become socioeconomically disadvantaged. With reduced opportunity to succeed in conventional ways, these individuals may be more likely to turn to antisocial or criminal methods to obtain money and status (see Agnew, 2006).

In the Cambridge Study in Delinquent Development, in which 411 males have been followed up from ages 8 to 48, boys identified by teachers as lacking in concentration or restless, those identified by parents, peers, or teachers as the most daring or risk taking, and those who were the most impulsive on psychomotor tests at ages 8–10, all tended to become offenders later in life. Later self-report measures of impulsiveness were also related to offending. High daring or risk taking, poor concentration, and restlessness all predicted both official

convictions and self-reported delinquency, and high daring was consistently one of the best independent predictors (e.g., Farrington et al., 2009).

A multi-method, multi-source assessment of impulsivity was carried out in the Pittsburgh Youth Study (White et al., 1994). The measures that were most strongly related to self-reported delinquency at ages 10 and 13 were teacher-rated impulsiveness (e.g., acts without thinking), self-reported impulsiveness (e.g., does things without planning), self-reported undercontrol (e.g., unable to delay gratification), motor restlessness (from videotaped observations), and psychomotor impulsiveness (from the Trail Making Test). Generally, the verbal behavior rating tests yielded stronger relationships with offending than the psychomotor performance tasks, suggesting that cognitive impulsiveness (based on thinking processes) was more relevant to delinquency than was behavioral impulsiveness (based on psychomotor test performance). The future time perception and delay of gratification tasks were only weakly related to self-reported offending.

Jolliffe and Farrington (2009) undertook a systematic review and meta-analysis of the relationship between early measures of impulsiveness and later violence using only data from prospective longitudinal studies. The results suggested that early measures of impulsiveness (measured as early as age 5) were quite strongly related to later violence (measured as late as age 40). While all measures of impulsiveness were associated with later violence, measures of high daring and risk taking were particularly strongly related to later violence. Jolliffe and Farrington suggested that high daring and risk taking might influence offending directly (because risk taking leads to offending), whereas the other forms of impulsiveness (e.g., poor concentration) might have a more muted effect through mediating variables such as school failure. Meta-analyses have also shown the link between low self-control and offending (e.g., Pratt and Cullen, 2000), and between attention-deficit hyperactivity disorder and offending (e.g., Pratt et al., 2002).

There have been many theories put forward to explain the link between impulsiveness and offending. One of the most popular suggests that impulsiveness reflects deficits in the executive functions of the brain, located in the frontal lobes (Moffitt, 1990). Persons with these neuropsychological deficits will tend to commit offenses because they have poor control over their behavior, a poor ability to consider the possible consequences of their acts, and a tendency to focus on immediate gratification (Morgan and Lillienfeld, 2000). There may also be an indirect link between neuropsychological deficits and offending that is mediated by hyperactivity and inattention in school and the resulting school failure. In discussing links between executive functions and offending, impulsiveness may be difficult to disentangle from intelligence, although Lynam and Moffitt (1995) argued that they were different constructs.

Empathy

There is a widespread belief that low empathy is an important personality trait that is related to offending. A distinction has often been drawn between cognitive empathy (i.e., understanding the emotions of another person) and affective empathy (i.e., actually experiencing another person's emotions). Therefore, those with high empathy should be less likely to offend because they are sensitized to the emotional impact of their actions on others. Those who lack empathy, on the other hand, can victimize others free from these internal cognitive and affective inhibitions. The theoretical relationship between low empathy and offending is more logical for interpersonal offenses such as violence and sex than for offenses where the victim is less obvious (e.g., shoplifting or drug possession).

Support for the inverse relationship between empathy and offending also comes from the study of psychopathy. Psychopathic personality is a constellation of psychological and behavioral traits that are linked to an increased likelihood of criminal and antisocial behavior (Skeem and Cooke, 2010). Those classified as psychopaths tend to be glib, superficial, and manipulative, but it is the lack of appropriate emotionality and empathy that especially characterizes this condition. It is well established that psychopaths are more violent and more likely to recidivate than nonpsychopaths, and it is the conspicuous lack of empathy of psychopaths that is often used to explain these behavioral outcomes. The childhood equivalent of psychopathic personality is callous-unemotional personality (Frick and White, 2008).

While there is clearly a strong theoretical relationship between low empathy and offending, the empirical evidence for this relationship is less impressive. For example, studies comparing empathy scores of offenders and nonoffenders have not produced consistently convincing results. This is true of studies comparing general offenders to nonoffenders (e.g., Goldstein and Higgins-D'Alessandro, 2001) as well as studies comparing sex offenders to nonoffenders (e.g., Hayashino et al., 1995). These findings are contrary to expectation, especially as it has long been assumed that sex offenders have significant deficits in empathy that directly contribute to their offending.

In an attempt to address this inconsistency, Jolliffe and Farrington (2004) carried out a systematic review and meta-analysis that included 35 studies comparing questionnaire measures of empathy with official records of offending. The results showed that low cognitive empathy was strongly related to offending, but low affective empathy was only weakly related. The findings of the systematic review also suggested that younger offenders and violent offenders were especially likely to have low empathy. In particular, however, the relationship between low empathy and offending was greatly reduced after controlling for intelligence or socioeconomic status, suggesting either that these might be more important risk factors for offending or that low empathy might mediate the relationship between these risk factors and offending.

Jolliffe and Farrington (2006) created the 20-item Basic Empathy Scale to measure cognitive and affective empathy. Jolliffe and Farrington (2007) showed that boys who self-reported offenses in the previous year had lower empathy, and this was especially the case for affective empathy. Girls who self-reported offenses did not have low empathy, but both boys and girls who self-reported violence did have low empathy. Also, boys and girls who were high-rate offenders also had significantly lower empathy (especially affective) compared to low-rate male and female offenders. These results provide more

convincing evidence of the importance of low empathy in relation to offending.

Eysenck's Theory

Before 1990, the most influential theory of personality and crime was that of Eysenck (1996). He viewed offending as natural and even rational, on the assumption that human beings were hedonistic, sought pleasure, and avoided pain. He assumed that delinquent acts, such as theft, violence, and vandalism, were essentially pleasurable or beneficial to the offender. In order to explain why everyone was not a criminal, Eysenck suggested that the hedonistic tendency to commit crimes was opposed by the conscience, which was viewed as a conditioned fear response.

Eysenck proposed that the conscience was built up in childhood. Each time a child committed a disapproved act and was punished by a parent, the pain and fear aroused in the child tended to become associated with the act by a process of classical (automatic) conditioning. After children had been punished several times for the same act, they felt fear when they next contemplated it, and this fear tended to stop them committing it. According to the theory, this conditioned fear response was the conscience, and it would be experienced subjectively as guilt if the child committed a disapproved act.

On the Eysenck theory, the people who commit offenses are those who have not built up strong consciences because either their conditioning was poor (i.e., they had not been taught right from wrong) or because they have inherently poor conditionability. Poor conditionability is linked to Eysenck's three dimensions of personality: extraversion (E; sensation-seeking, sociability), neuroticism (N; anxiety, depression), and psychoticism (P; tough-mindedness, low empathy).

According to Eysenck, people who are high on E build up conditioned responses less well, because they have low levels of cortical arousal. People who are high on N also condition less well, because their high resting level of anxiety interferes with their conditioning. Also, since N acts as a drive, reinforcing existing behavioral tendencies, neurotic extraverts should be particularly criminal. Eysenck also predicted that people who are high on P would tend to be offenders, because the traits included in his definition of psychoticism (emotional coldness, low empathy, high aggression) were typical of criminals. However, the meaning of the P scale is unclear, and it might perhaps be more accurately labeled as psychopathy. Zuckerman (1989) suggested that it should be termed "impulsive unsocialized sensation seeking."

A review of studies relating Eysenck's personality dimensions to official and self-reported offending concluded that high N (but not E) was related to official offending, while high E (but not N) was related to self-reported offending (Farrington et al., 1982). High P was related to both, but this could have been a tautological result, since many of the items on the P scale are connected with antisocial behavior, or were selected in light of their ability to discriminate between prisoners and nonprisoners. In the prospective longitudinal study of London boys, those high on both E and N tended to be juvenile self-reported offenders, adult official offenders, and adult self-reported offenders, but not juvenile official offenders. These relationships held independently of other criminogenic risk factors, such as low family income, low intelligence, and poor parental child-rearing behavior.

When individual items of the personality questionnaire were studied, however, it was clear that the significant relationships were caused by the items measuring impulsiveness (e.g., doing things quickly without stopping to think). Therefore, it seems likely that research inspired by the Eysenck theory essentially confirms the link between impulsiveness and offending. More recent empirical studies (e.g., Carrasco et al., 2006) and meta-analyses (e.g., Cale, 2006) that have compared Eysenck's dimensions to crime and antisocial behavior have given further support to this conclusion.

The 'Big Five'

In recent years the Five Factor Model (FFM) of personality has replaced Eysenck's three-factor theory as the primary model of personality traits (McCrae and Costa, 1997). The FFM includes the dimensions of E and N (defined similarly to those of Eysenck), as well as Agreeableness (A; altruism, modesty), openness (O; imagination, aesthetic sensitivity), and conscientiousness (C; self-discipline, competence). Research has suggested that Eysenck's P is inversely related to both A and C (Costa et al., 1991). Controversially, McCrae et al. (2000) argued that these personality dimensions are biologically based tendencies that follow intrinsic developmental pathways independently of environmental influences. McCrae and Costa (1997) also found that the same five factors emerged in several different countries.

Relatively few studies have related the 'Big Five' personality dimensions to offending. In the Pittsburgh Youth Study, John et al. (1994) found that the most delinquent boys scored significantly lower on agreeableness, conscientiousness, and openness and significantly higher on extraversion. In Australia, Heaven (1996) reported that agreeableness and conscientiousness were most strongly (negatively) correlated with delinquency. Similarly, Van Dam et al. (2005) in the Netherlands reported that students scored significantly higher on agreeableness and openness than juvenile delinquents.

In their meta-analysis relating a number of personality scales to antisocial behavior, Miller and Lynam (2001) concluded that low agreeableness and low consciousness were significantly related to antisocial behavior, while neuroticism was only weakly related and extraversion was not related. In the most recent meta-analysis, Jones et al. (2011) concluded that agreeableness and conscientiousness were negatively related to antisocial behavior and aggression, while neuroticism was positively correlated. The most important facets that were related to antisocial behavior were hostility and impulsiveness (N), straightforwardness and compliance (A; negatively), and dutifulness and deliberation (C; negatively).

Future Directions

More research is needed on the theoretical linkages between personality constructs and offending, and on the biological bases of personality constructs. Prospective longitudinal

studies are especially needed in which personality traits are measured early in life and related to later offending, in order to investigate the relative importance of biological, individual, family, peer, and school influences on personality and crime. Such studies should especially investigate whether changes in personality are followed by changes in offending.

Research on childhood temperament suggests that potential offenders can be identified early in life and that efforts should be made to change young children who have uninhibited and uncontrolled temperaments. The evidence from prospective longitudinal studies is clear in showing that high impulsivity is related to later offending. This implies that interventions that target impulsiveness, such as child skills training (e.g., Augimeri et al., 2007; Lösel and Beelman, 2006), should be effective in reducing later offending. Empathy has yet to be included in such prospective longitudinal studies, so it is difficult to determine how, or indeed if, low empathy in childhood is related to adult offending. Research on personality and crime should be useful in matching types of people to types of interventions because it seems likely that different personality types would interact differently with different criminological risk factors, and therefore that interventions should be tailored to personalities. Ideally, personality assessment should be included in any intervention program.

There is no doubt that personality influences behavior, including offending behavior. However, there is still the danger that measures such as a 'difficult temperament' or 'low agreeableness' are symptoms of the same underlying construct (e.g., an antisocial personality) as is offending, so that these personality traits cannot be regarded as causes of offending. The one personality trait that probably causes offending is high impulsiveness, and it seems likely that low empathy is also an important cause. If high impulsiveness and low empathy have causal effects on offending, targeting them in intervention programs should have desirable effects in reducing crime and associated types of social problems.

Personality and Economics

Abstract

Mainstream modern economics studies the decision behavior of rational agents. In a prototypical model, individuals take four sets of *primitives* (preferences, information, technology, and incentive constraints) as given, and choose the best feasible action in each situation. This article summarizes how economic theories have incorporated findings and ideas from personality psychology in each of these four types of primitives. In the discussion, it will become clear that the introduction of some aspects of personality into standard mainstream economic models has seriously challenged their scientific validity, it being one of the most controversial topics in the field.

Introduction

Modern economics aims to study the decision behavior of individuals (and more generally, of economic agents). The foundation of the field is the 'theory of rational choice,' which states that agents are able to order their possible actions into a choice set according to a unidimensional criterion. (This criterion is called utility, when the decision-maker is the consumer or the household.) In a typical decision-making problem, four sets of objects are taken as given by the agent when choosing the best action to take: (1) Individual *Preferences*, which comprise tastes, attitudes toward risk, and the intertemporal discount factor (the rate at which the individual is willing to trade present pleasure for future pleasure), among others; (2) *Information and Beliefs*, meaning that agents are assumed to act on what they think is best for them (instead of on what is truly best); (3) *Technology*, that determines what individuals can do in a given situation; and (4) *Incentives*, which modify the payoffs of specific actions and contribute, together with preferences, to forming the individual ranking of actions coherent with the aforementioned criterion. These four objects are called the *primitives* of the decision behavior in an economic model.

Psychology, in turn, investigates the mental processes that determine behavior in general. As we will discuss in this article, personality traits may affect the decision problem in different ways, sometimes being central to the determination of the observed economic behavior. Whenever possible, this article attempts to make connections between the ongoing discussion in economics and the personal–situational debate that dominated the field of psychology of personality throughout the twentieth century. Although the debate is grounded in great differences about how people conduct themselves, it was propelled by empirical evidence that suffers from a fundamental identification problem: there are two causes for a single effect. One must assume that one of the sources is of little relevance in order to learn about the other from observed effect. Understanding the motivations behind each theoretical view and how they were adapted to have empirical content is crucial to further interpret how individual intrinsic characteristics (which I call personality traits) affect behavior, and how their importance compares to that of environmental variables. The next section briefly exposes the challenges involved in empirically identifying causal relations between personality attributes and observed decision behavior.

The third section of this article discusses how economists have included personality traits in the *primitives* of economic behavior, and the related empirical evidence. The last section concludes and speculates about the future of the field.

The Fundamental Identification Problem in the Search for Causal Relations between Personality Traits and Individual Economic Outcomes

Empirical attempts at estimating the structure of personality and the role of its elements in the determination of observed behavior typically face two types of obstacles. First, personality is a multidimensional concept that involves multiple categories of objects, each of them with multiple elements. In an influential study, Roberts (2006) concludes that personality is composed of traits (e.g., the 'Big Five' factors), motives and values (such as goals and interests), abilities (e.g., factor 'g,' verbal and spatial), and narratives (stories, significant memories, and scripts). Other approaches use different taxonomies, but usually describe personality in a multidimensional fashion as well. Existent heterogeneity in observed behavior is generally the result of heterogeneity in personality and the prevalent context/situation at the moment the behavior was registered. If one could measure all relevant aspects of personality and context, the causal effect of an element of personality (let us call it 'P') in the determination of a given behavior or outcome (y) could be computed by the direct comparison between the distribution of the respective behavior or outcome in subsamples of the population characterized by different levels of this element of personality, keeping other components of personality (Q) and environmental conditions (C) constant (i.e., the comparison between $f(Y|P=p;\ Q=q,\ C=c)$ and $f(Y|P=p';\ Q=q,\ C=c)$). In reality many relevant aspects of personality and context are not measurable, and only subsets Q^o of Q and C^o of C are effectively observed. Thus, the comparison between $f(Y|P=p;\ Q^o=q^o,\ C^o=c^o)$ and $f(Y|P=p';\ Q=q,\ C=c)$ can only be interpreted as a causal consequence of changes in P on Y if one assumes that the unobserved parts of Q and C are constant or statistically unrelated to P. To

illustrate this point, suppose that Y is the final GPA obtained in high school and P is a measure of IQ. The fact that people with low IQ have lower average GPA can only be interpreted as a causal effect if other personality elements and the context were similar across people with different IQ levels. Conversely, if IQ were systematically related to self-esteem, it would not be clear if the differences in GPA as measured by the IQ level were a consequence of differences in IQ or in self-esteem.

As stated above, economics aims to explain the decision behavior through four sets of *primitives*. Each of these *primitives* contains elements of environment (context/situation) and personality. Theories and models that emphasize the importance of variations in the environment in rationalizing heterogeneity in behavior tend to use the hypothesis that personality is constant or displays only minor differences among agents, so that differences in behavior could be mostly attributed to differences in the environment (and the opposite holds for models that explain economic behavior through individual differences in personality).

The second identification problem holds that most of the personality components of interest are not directly measurable. Both classical test theory and item response theory psychometrics consider behavior to be a function of a low-dimensional set of latent personality traits, and use statistical filters to compute the individual value of such traits from a set of observed behavior measurements. Two conditions are necessary for this strategy to work. On the one hand, behaviors must be an invertible function of elements of personality, so that individuals with identical observed behaviors have the same personality structure (ideally, once controlled for environmental conditions). On the other hand, if two or more personality components determine the same observed behavior, identification of the individual personality structure depends on the number of measured behaviors being at least as large as the number of personality elements one wishes to estimate. Since few theorists are willing to postulate ex-ante the number of relevant components of the personality structure, estimation of these components relies only on empirical regularities of the data revealed through the chosen statistical filters (e.g., the Big Five factors of personality, revealed by linear factor analysis applied to inventories based on the lexical hypothesis (see Allport and Odbert, 1936)).

Relevant for our discussion is to note that elements of personality were incorporated into mainstream economics in different ways, depending on the underlined economic question. Sometimes, personality traits are assumed to be stable, in order to allow for a deeper analysis of the relationship between context variables on the decision behavior. In other circumstances, personality plays a central role in determining behavior, being even treated as subject to modifications.

The Inclusion of Personality in Economic Models

Research in psychology generally seeks to explain the relationship between mental functioning and (observed) behavior. An economic model that realistically describes the individual decision behavior would likely be incomplete if it ignored the findings of personality psychologists. In fact, aspects of personality are an important ingredient of all *primitives* of economic models. This section shows how personality relates with each of the four *primitives* described in the Introduction.

Personality and Preferences

Individual preferences are a system of relations governed by intrinsic characteristics of economic agents, which inform how the outcomes of actions translate into payoffs (be it utility, satisfaction, or happiness). In a mainstream economic model, preferences determine how an individual ranks the existing actions in a given situation. Aspects of preferences include *tastes*, *attitudes toward risk*, and *intertemporal rate of discount* (the rate at which an individual is willing to trade present satisfaction for future satisfaction), among others. In principle, all personality traits and abilities that affect the way individuals order their actions are also part of preferences.

Although the importance of tastes in determining the allocation of scarce resources in an economy has been noticed since Adam Smith's work (see Rosenberg, 1968), it was after the utilitarian revolution that it became a key feature of decision behavior models. The statements that "agents do what is best for them" and that "aggregate behavior is no more than the result of a set of individual actions" are central in both microeconomic and macroeconomic models.

It is important to mention, however, that the supremacy of the rational choice theory (RCT) in economics did not come without controversy. As simple as it is, the RCT departs from two basic axioms (*Completeness*: agents can compare any pair of existing actions, A and B, and rank their respective payoffs in terms of their utilities; and *Transitivity*: for every triple (A, B, and C), if A's payoff is at least as high as B's, and B's payoff is at least as high as C's, then A's payoff is at least as high as C's.) to guarantee the existence of an individual ranking of rewards, each of which correspond to an existing action. In a given situation, a subset of such actions is available, and individuals choose the best action in this subset. The problem with this approach is that it is tautological without further restrictions (see Sen, 1973; Marx, 1867), meaning that every observed behavior could be explained by some structure of preferences in every specific context. The empirical content of economic models typically comes from additional assumptions on preferences, which have been subject to debate.

In fact, most economic models assume that preferences are to some extent *stable*, so that differences in the decision behavior are mostly due to differences in the environment (e.g., technology and incentives). Although stability has been implicitly assumed since the first empirical economic models, it was with Stigler and Becker's (1977) influential paper that the formal role of this hypothesis was established. The authors advocated not only that individual preferences are fully stable, both throughout the life cycle and across state contingencies, but also that heterogeneity of preferences among economic agents is small and negligible in terms of explaining the observed heterogeneity in behavior. The authors respond to common criticisms that addiction, advertisements, cultural changes, fashion, and the invention of new goods would transform tastes, by saying that it is not the tastes that are modified by these factors but rather the information and learning about the actions and their payoffs.

The discussion around *stability* that followed the Stigler–Becker argument (and much of Becker's subsequent work) resembles to a large extent the personal–situation debate in psychology. In both cases, heterogeneity in individual traits and in context generates heterogeneity in behavior, but as discussed in the previous section, one must impose restrictions in one type of heterogeneity in order to recover the other from the observed behavior. An economic theory that stated individual decision behavior is mostly driven by tastes is of no use for policymaking or for understanding the role of economic variables (such as prices and income) in the process. In general, economists study decision behavior in order to investigate which type of interventions could improve welfare (at the individual or aggregate level). Almlund et al. (2011) use a similar argument to suggest that "The debate over the relative importance of person and situation in the 1960s and 1970s reflected deeper currents in psychology and social science more generally, that still run strong. (…) Behaviorism (…) posited that experience explains all aspects of behavior. There was the widely held notion that situation and experience were all powerful—that people were born as blank slates. This captured the interventionist spirit of the times."

Although the textbook hegemony and the Nobel Prize (to both Stigler – in 1982 – and Becker – in 1992) confer a privileged position upon their point of view, their antagonists are no less influential. Behavioral economists and psychologists such as Daniel Kahneman (also a Nobelist, 2002) and Amos Tversky documented the existence of a type of cognitive bias called *framing effect*, i.e., the fact that the agent's decision over the same alternatives depends on the way these alternatives are offered to the agent. (Many *paradoxes* of preferences studied in the literature are the result of a framing effect. See Tversky and Kahneman, 1981.) In a similar vein, Kahneman, Tversky, Robert Thaler, and coauthors investigated the *endowment effect* (see Thaler, 1980; Kahneman and Tversky, 1979; Kahneman et al., 1990). In a context of consumption, the endowment effect implies that a person is more willing to pay to retain a good than to acquire it, suggesting that attachment and loss aversion are important aspects of consumer behavior.

The axiom of transitivity is a second major source of disagreement between mainstream economists and their critics. May (1954), and especially Tversky (1969) exposed individuals to specific series of risky gambles in a laboratory experiment to show that individuals seemed to systematically make choices in an intransitive way. Tversky's paper inaugurated a prolix research agenda in the field of behavioral economics in which many researchers tried to prove transitivity is unrealistic, methodically replied by mainstream economists (mostly on the basis of the weak external validity and adequacy to reality of such laboratory experiments).

Tversky rationalized his findings by proposing an alternative decision theory for risky actions. According to him, agents first order such actions by their probabilities of positive outcomes and expected pleasure, and afterward by expected loss (lexicographic semiorder interpretation). This was a sharp contrast with the prevailing expected utility (EU) theory, first proposed in 1738 by Daniel Bernoulli (1954) (as a response to the St. Petersburg Paradox (posed by his uncle, Nicolas, in 1713)), and broadly used to model decisions under uncertainty. The EU hypothesis states that agents compare the expected payoff of every possible action in order to decide what to do, so that if two states of nature deliver a gain and a loss of the same magnitude with equal probability, they should cancel each other out. Indeed, risk aversion and decision under uncertainty are a third major source of controversy about preferences. Tversky's original explanation was generalized in a joint work with Kahneman (1979) who originated the *Prospect Theory*, within which agents have reference points and behave in order to minimize expected loss (instead of maximizing EU). Typically, losses hurt more than the pleasure associated to gains (loss aversion, which was also formulated by Akerlof and Yellen (1985), but in a slightly different way). Prospective theorists also seek to explain how agents set the reference utility point, a topic in which *focusing effects* and *anchoring effects* (giving disproportional importance to a specific piece of information and to the first information when setting the reference point, respectively) play important roles.

Behavioral economics has not only challenged the mainstream view about decision-making in situations involving *risk* (i.e., when actions' payoffs are unknown ex-ante, but agents know their respective probabilities), but also proposed a new theory about choice involving *uncertainty* (when even probabilities are unknown). Tversky and Fox (1995), for instance, show that if two lotteries are equally valuable to agents when evaluated in isolation but the underlined probabilities of one of them are unknown, then individuals systematically choose the other when both alternatives are offered. After this work, risk (or loss) aversion and ambiguity aversion were considered two different traits of preferences in many papers in economics.

A related but different cause of divergence in terms of preferences is the description of *intertemporal decision behavior*. The mainstream view usually assumes additive discounted intertemporal preferences, meaning that: (1) future satisfaction does not depend upon current satisfaction and depends on the current state of nature only to the extent that it affects feasible actions in the future; and (2) the rate at which individuals are willing to trade present satisfaction for satisfaction in the next period is the same as in any two subsequent periods of life. (Some authors put it as a requirement for preferences to be *dynamically consistent*, i.e., for the optimal decision in a contingency decision plan not to depend on the time or history of realizations of the contingencies. Lack of dynamic consistency (such as that produced by hyperbolic discounting) may generate opportunities of *arbitrage* in the credit and financial markets.) Critics of this view generally argue that people are *present-biased* (see Thaler and Shefrin, 1981), and that the willingness to trade the present for next-period pleasure is much lower than the respective rate between two subsequent future periods. This fact was mathematically formalized through the *hyperbolic discounting utility* theory (Laibson, 1997; Akerlof, 1991), and has been related to psychological concepts of delay of gratification, self-regulation, and self-control (Akerlof, 2002).

Finally, economists have progressively adapted the pure rational choice formulation to account for social aspects of decision. The study of social preferences can be divided into two major groups: (1) situations in which the individual's attitudes affect others' welfare and actions (which may alter the individual's behavior, if he/she cares about the other's welfare, or if the other's actions have consequences for his/her satisfaction); and (2) situations in which the other's (established) status

directly affects the individual's preferences (see Chapters 1 (by Kolm) and 8 (by Fehr and Schmidt) of the *Handbook of the Economics of Giving, Altruism and Reciprocity* (2006), for a recent and broader overview).

In the real world, individuals often give gifts and help people with no expectations of receiving something in return. In an early formulation, Becker (1974) says individuals acquire a psychic good ('a warm glow'), so that gifts and help are no evidence of altruism. Levine (1998) proposes a model in which other people's satisfaction directly affects individual welfare, introducing altruism directly into the structure of preferences. Akerlof (1982) investigated why some firms would pay above-market wages to their workers, and introduced the idea of reciprocity, fairness, and attachment to social norms to modern economic models. According to him, "a worker's effort depends upon the norms determining a fair day's work." Firms would then pay higher wages in order to affect those norms, and receive higher effort in exchange. (Other authors (e.g., Shapiro and Stiglitz, 1984) examined the same fact, which is now known as the 'wage-efficiency theory.' In his Nobel Prize lecture (2001), Akerlof advocates the inclusion of *reciprocity*, *fairness*, and *adherence to group norms* in other contexts involving apparently *irrational* decision behavior.)

In a different direction, Simon (1947) and Akerlof (1991) studied the role of *authority and obedience* in decision-making at the organizational level. The higher-ranked professional usually expects obedience, and the subordinate is usually willing to obey. Authority and obedience therefore influence the actions of all actors, and is the cause and effect of the establishment of goals and values in an organizational environment, as well as of the socioprofessional relationships and reward systems.

The role of distributive issues in shaping preferences has also been an active topic of research with interactions with the psychology of personality. On the one hand, there is an old tradition of economists (going back at least to Veblen, 1899) who argue that an individual's welfare depends not only on his/her income (and more generally, resources and opportunities), but also on relative income (or relative position in society), bringing the concept of *envy* to the heart of the decision problem. On the other hand, Fehr and Schmidt (1999) and Bolton and Ockenfels (2000), among others, suggest that inequality hurts an individual's welfare regardless of his/her social position, proposing *inequality aversion* should also be included in the structure of individual preferences.

Many papers have surveyed the empirical evidence concerning the validity of mainstream and alternative assumptions about preferences, and their relation with personality traits. Most of the work on this matter was developed through laboratory experiments, among which Rabin (1998), Sendhil Mullainathan and Thaler (2001), and Camerer (2006) are good references. DellaVigna (2009) provides new evidence coming from nonlaboratory data sets.

Beliefs and Information

Economic theory has truly experienced a revolution over the last 40 years, in which the availability of information, learning, and belief formation processes was definitely incorporated into the description of decision behavior. Succinctly speaking, researchers have realized that individuals make decisions based on what they know about the world and think is optimal for them (even though this may not in fact be true). Knowledge of the world depends on restrictions on information disclosure and processing, on the beliefs that agents have about the future and about how other people react to their actions, and both available information and beliefs are subject to learning over time.

Herbert Simon (also a Nobelist, 1978) has argued that an individual's capacity to process and order the payoffs of all possible actions in a given context is limited, and agents therefore develop strategies to overcome such difficulties. Simon's contribution became what is now known as the *Bounded Rationality* agenda. In dealing with information processing and availability limitations, individuals build strategies that usually involve subjective beliefs about the result of their actions; the basis of the *Subjective Expected Utility* theory.

The inability to process all available information is also the focus of the literature on *Myopic Behavior*, which explores the fact that agents do not forecast or compute all possible consequences of their actions. A well-studied example of myopic behavior is the monetary illusion (the fact that in some circumstances agents decide based on the nominal value – instead of the real value – of economic variables). Both bounded rationality and myopic behavior have a strong component of cognitive limitation, and may be reinforced by characteristics such as self-control and anxiety (see Fisher (1928), Fehr and Tyran (2001), and Shafir et al. (1997) for both theoretical end empirical discussions on myopic behavior).

On a different front, behavioral economists document and theorize about the systematic formation of incorrect beliefs. Overconfidence (part of self-perception and the locus of control) distorts expected payoffs and directly affects decisions. Excessive reliance on anecdotic situations and the extrapolation of its consequences to other contexts is a second source of biased beliefs. Underestimation of one's ability to adapt to new circumstances (which sometimes justify overreaction to adverse shocks) also changes expectations about the payoffs of many actions. These three types of incorrect beliefs are all surveyed in DellaVigna (2009). Overall, many of the documented cognitive biases are potential sources of incorrect beliefs, with consequences on decision making.

Misinterpretation of the information may also produce incorrect beliefs, being also related to a difficulty in information processing (related therefore to cognitive limitations). A popular topic in empirical work in economics is self-selection and survivorship (see Heckman, 1979; Heckman and Sedlacek, 1985; Elandt-Johnson and Johnson, 1999). People choose what to do based on the observation of a world of winners. Observed distributions of wages and profits, for example, do not reflect the respective ex-ante payoffs of prospective workers and firms in their decisions on supplying labor or starting a business. The outcomes of the losers were not there, because they have been eliminated from the game by market forces. Researchers should be able to separate the statistical overoptimism, produced by the misinterpretation of reality, from the true overoptimism, determined by a personality trait. Other examples of statistical biases (studied in economics) that may distort beliefs are statistical discrimination (Becker, 1993) and regression to the mean (Galton, 1869; Samuels, 1991).

Technology and Incentives

In many situations, the individual decision problem is constrained by incentive restrictions imposed by others' responses to his/her actions. Such responses, in their turn, are also the result of the rational decisions of other agents, and therefore depend on preferences, beliefs, and technologies that characterize their decision problems. Since others' preferences and beliefs are deeply influenced by their own personality traits, incentive constraints are influenced by them as well. Bowles et al. (2001) go a step further to study how certain specific personality attributes make people more susceptible and reactive to changes in the structure of incentives. In their paper, they argue that the workers with external locus of control and low self-efficacy expend less effort in their jobs and do not react to incentives, since they do not believe that their actions are effective. Individuals who value future pleasure and have a sense of shame in being without a job are also more sensitive to incentives. In a different approach, Tversky and Kahneman (1974) highlight the importance of social pressure and persuasion in workplace performances and voting decisions.

Labor earnings are the main portion of personal income, an important technological constraint (to the extent that available income strongly restricts the actions one can choose in many contexts). Besides being affected by incentive constraints (which are subject to the influence of personality), wages are usually taken as a function of the set of individual productive attributes, which may include personality traits as well. In fact, a promising recent branch of economics literature has explored this argument, and shown that the so-called *noncognitive* abilities and traits are at least as important as the *cognitive* ones in the formation of wages (see Heckman et al., 2006).

In a comprehensive survey of the empirical evidence of the predictive power of personality traits, Almlund et al. (2011) show that conscientiousness and its facets, as well as some facets of neuroticism (the locus of control and self-esteem) are important determinants for job performance and wages.

Previous literature about individual outcomes related to the stock of human capital also investigated its impact on health, education, family formation, and involvement with violence. Being part of human capital, it is not surprising that many researchers documented the relationship between personality traits and these outcomes. Almlund et al. (2011) summarized this evidence as follows:

- *Education*: Openness to experience and conscientiousness consistently appear to be important predictors of educational attainment, although most empirical studies cannot convincingly prove this relationship to be causal. The locus of control (sometimes taken as a facet of neuroticism) is also related to attainment, and this evidence appears in different countries. Regarding grades, conscientiousness (especially self-control) is the most robust predictor, but the authors warn against the risk of teachers using grades to directly punish/reward attributes not related to academic achievement. Studies that used standardized test scores roughly confirmed the relevance of conscientiousness, and stressed the role of attention, possibly one of its facets.
- *Health*: The facets of openness to experience, conscientiousness, and agreeableness are associated with longer lives, whereas the opposite happens with aspects of neuroticism. Agreeableness and conscientiousness also correlate with involvement with drugs, tobacco, and alcohol.
- *Violence*: Self-control seems to be the main individual trait that determines crime and involvement with violent episodes.

When understood as part of the individual stock of human capital, personality attributes are assumed to be subject to investments in their improvement. In sharp contrast to the way mainstream economics treats these characteristics when talking about their influence in other primitives, here personality is not only treated as changeable, but also people have a certain amount of control over their evolution across the life cycle. Cunha et al. (2010) built and estimated an economic model of human capital accumulation in which individuals could invest in both cognitive and noncognitive characteristics. They conclude that both types of attributes are relevant determinants of many individual outcomes, and that people with higher initial levels of (cognitive and noncognitive) skills benefited more from an investment in human capital ('skills beget skills'). Public and private policies and programs have also proved to be effective in changing personality traits (Heckman et al., 2010; Gottschalk, 2005; Diamond et al., 2007).

Conclusions

The goal of this article was to summarize the economic theories and empirical evidence that dedicate to personality a predominant role in the determination of decision behavior and economic outcomes. Most of the discussion cited herein has emerged from and developed predominantly among the so-called 'behavioral economists,' who have systematically challenged the mainstream view in economics, in which economic behavior is mainly driven by environmental variables. The debate is old, but recent research has boosted the field and brought new empirical evidence.

While the textbook economic models assume that preferences (intrinsic personal characteristics, which include personality traits) are stable over time and display little heterogeneity across agents, behavioral economics relativize this scenario by showing that circumstances often affect the way individuals order their preferred actions. While mainstream economics suggests that individuals share common beliefs about the world, its critics argue in favor of subjective beliefs and an imperfect ability of processing information. In spite of the existing divergences, most economists seek to identify environmental variables that affect behavior, and my interpretation of the controversy concerns whether the environment only affects decision through technology (restrictions that constrain individuals' sets of choice), or whether it can also directly influence the way agents rank their available actions' payoffs in order to decide what to do.

A third agenda relating personality to economics has emerged in the last 20 years, incorporating personality traits into the well-established human capital theory. Human capital is usually defined as the set of productive traits and abilities which are then used to produce goods (with wages as the

respective reward), health, noninvolvement with violence, family stability, and well-being in general. Contrary to other economic views of personality, families and the state can invest in the improvement of the personality traits of their members, and do so in a rational way, aiming to maximize intertemporal satisfaction.

In the present context, we know that noncognitive attributes as a whole contribute approximately as much as cognitive aspects to academic achievement, as measured by grades, dropout rates, and educational levels achieved. Noncognitive characteristics are also rewarded in the labor market in the form of higher wages and shorter unemployment spells. In other investigated dimensions (health, involvement with crime and violence), the role of noncognitive attributes surpasses that of abstract intelligence, providing higher levels of satisfaction. Some researchers add to these facts the interdisciplinary evidence that cognitive traits crystallize earlier in life than the noncognitive ones, to advocate that public policy oriented toward equality should prioritize investments in noncognitive skills, if the target group is composed of adolescents and adults.

Finally, history has shown that many theoretical disagreements can survive only while data are not available to test their respective predictions. Measuring personality traits has always been a difficult task, but the intensification of the interdisciplinary dialogue may bring new methods and empirical content to the existing theories that help to overcome these difficulties.

Personality and Educational Outcomes

Abstract

Among the most important outcomes for individuals and countries are those linked with education, and recent research has established that these outcomes are reliably correlated with personality measures based upon the five-factor model. Conscientiousness measures are the most strongly associated with educational outcomes at all educational levels, apparently due to conscientiousness being based upon effortful control and links with self-regulation of learning activities. Openness is next most important, resulting from associations with curiosity and motivation to learn. Correlations of academic performance with self-rated agreeableness, extraversion, and emotional stability decline at higher educational levels. Other-rated personality measures typically provide stronger, more consistent correlations with educational outcomes. Although intelligence affects some of these relationships, educational outcomes are independently linked with personality with effect sizes comparable with correlations with intelligence. Consequently, personality has a crucial role in education.

Educational outcomes are among the most important factors in advanced economies, both for individuals and nations. Better-educated populations result in greater economic growth (Hanushek and Woessmann, 2012), while an individual level, achievement on grades and grade point average (GPA) reflects not only learning achievement but also predicts later work performance (Roth et al., 1996), and occupational prestige and status (Strenze, 2007). Consequently, recent work that has established an important role for personality and related factors with respect to GPA and other educational outcomes assumes much more than academic interest.

Cognitive and Noncognitive Predictors of Educational Outcomes

Early research on predictors of educational outcomes led to the delineation of the preeminent feature of individual differences research within both psychology and education, namely intelligence. The pioneering work of Binet and Simon (1905) aimed at predicting students' potential for succeeding at school, the end-result of which were the Stanford–Binet Intelligence Scales (Wolf, 1973), while Spearman identified his *g* factor of intelligence by factor-analyzing educational performance measures (Spearman, 1927). These cognitively based individual difference factors have long been recognized as important within educational settings.

Systematic research aimed at identifying "noncognitive skills" (Heckman and Rubinstein, 2001) relevant to education has continued for at least as long as have explorations of intelligence. Yet although early research by Webb (1915) produced substantial associations between personality ratings and educational performance, most reviewers reported inconsistent results (Harris, 1940; Margrain, 1978), largely due to the lack of coherent organizing frameworks for personality measurement, effectively precluding comparison of results from different studies. In response, De Raad and Schouwenburg (1996) argued for the use of comprehensive, reliable personality factor structures for systematically reviewing this research. This recognition, together with comparable research into links between personality and performance in other settings, especially the workplace (Barrick and Mount, 1991), provided the inspiration for recent reviews that have established consistent links between personality and educational outcomes.

The currently dominant model of personality, which has enabled recent integrative reviews, is the five-factor model (FFM). Norman (1963) is often credited with proposing the FFM, but hints of this model were provided as early as Webb (1915). The factors within the FFM are conscientiousness (organized, responsible, and self-disciplined); agreeableness (sympathetic, warm, and kind); emotional stability (relaxed and patient) but often identified by its opposite pole labeled as neuroticism (moody, irritable, and envious); extraversion (talkative and sociable); and openness (intellect and creativity, smart, innovative, and inquisitive) (Saucier and Goldberg, 1996).

Although other models of personality have been developed, and there are significant concerns about its cross-cultural validity, the FFM remains the dominant model for personality research generally, and within educational research specifically, with the overwhelming majority of studies of personality and educational outcomes using FFM-based measures (Richardson et al., 2012).

FFM and Educational Outcomes

The first systematic review of correlations with educational outcomes that was organized on the basis of the FFM was presented by Hough et al. (1990), but this has recently been followed by more rigorous and exhaustive reviews (Poropat, 2009, 2014a,b; Richardson et al., 2012). Collectively, these have demonstrated that personality has reliable and important associations with educational outcomes.

Conscientiousness

Using a precursor of factor analysis, Webb (1915) was the first researcher to identify a 'factor' approximating conscientiousness, by proposing the existence of a variable reflecting

'persistence of motives,' or alternatively, "*consistency of action resulting from deliberate volition, or will*" (p. 60, italics in the original): in other words, a *w* factor as a complement to Spearman's *g*, and incorporating a rating scale labeled *conscientiousness*. The FFM factor of the same name has been reported as having the strongest correlation with educational outcomes, ranging from grades (Hough et al., 1990; Poropat, 2009, 2014a,b; Richardson et al., 2012), to workplace-learning achievements (Barrick et al., 2001), and within educational settings there has been more research on conscientiousness than any other personality variable (Poropat, 2009, 2014a,b; Richardson et al., 2012).

Conscientiousness has been shown to have reliable correlations with academic performance at primary, secondary, and tertiary levels of education (Poropat, 2009), and this pattern has been observed across cultures (Kaufman et al., 2008; Poropat, 2009). Typically, research on personality uses self-rated measures, yet correlations of academic performance with conscientiousness increase substantially when someone other than the student rates their personality. Notably, observed correlations (i.e., uncorrected for measurement artifacts) of academic performance with other-rated conscientiousness exceed comparable correlations with intelligence at secondary and tertiary levels of education (Poropat, 2014a,b).

At the behavioral level, conscientiousness is associated with compliance with social norms, setting and pursuing goals, and operating in a purposeful manner (Roberts et al., 2009). Goal-setting reliably predicts school achievement, as do a range of other conscientiousness-related behaviors and activities, including self-monitoring and self-management, planfully and persistently following a course of action regardless of distractions, and noticing and correcting errors (Hattie, 2009). So, in many ways the actions of the conscientious student mirror those that educators should encourage in their students in order to achieve better learning outcomes.

At a deeper level, conscientiousness has been closely associated with *effortful control*, a component of individual temperament (Rothbart, 2007). Effortful control has been posited to encompass elements such as the ability to control attention and inhibit inappropriate responses, and consequently to self-regulate and persist with activities. The capacities associated with effortful control are apparently based upon executive attention activities within the brain (Posner and Rothbart, 2009), which have been explicitly linked with conscientiousness (Rothbart, 2007). These abilities play an important role in the relationship between conscientiousness and educational outcomes (Bidjerano and Dai, 2007; Eilam et al., 2009; Richardson et al., 2012). For example, more conscientious students are more likely to stay enrolled (Komarraju and Karau, 2005; Sitzmann, 2012), and are better at managing and allocating their time to enable them to study more (MacCann et al., 2012a; Poropat, 2011b; Poropat and Jones, 2009). But more conscientious students also study more effectively (Bidjerano and Dai, 2007), adapting their activities to specific learning requirements (Swanberg and Martinsen, 2010), resulting in better outcomes (Zhang et al., 2011).

Conscientiousness is also linked with intrinsic motivation to learn (Clark and Schroth, 2010), both initially and subsequent to formal educational activities, when more conscientious students are more likely to focus on activities that will assist them in applying their learning beyond educational settings (Yamkovenko and Holton, 2010). At the same time, conscientiousness is valuable in assisting students to control negative responses to learning, with more conscientious students being more able to manage stress and to refocus from stressors to their learning-based tasks (Saklofske et al., 2012). This is aided by the use of problem-focused coping (MacCann et al., 2012b), including shifting focus from performance goals to learning goals, which in turn reduces levels of stress and tension for students who are more conscientious (Cianci et al., 2010) resulting in these students feeling better within themselves (MacCann et al., 2012b). Thus, conscientiousness aids learning in many ways, which helps to explain why it is the FFM dimension that has the strongest associations with education outcomes.

Agreeableness

Agreeableness is associated with the ability of students to develop and maintain positive relationships with others, which seems to account for links between agreeableness and learning (Saklofske et al., 2012), because the adaptability associated with agreeableness makes it easier for students to make extra efforts outside of formal teaching, including making greater efforts with homework (Lubbers et al., 2010). Yet more agreeable students also appear to be generally better at time management and independent effort regulation, potentially contributing to later academic performance (Bidjerano and Dai, 2007). More agreeable students have a greater ability to internalize the interests of others, enabling them to more readily recognize and behaviorally comply with extrinsic demands even when they conflict with personal interests (Clark and Schroth, 2010). These factors assist students to learn more effectively in groups, which is important given that group learning is often more effective than individual learning (Michael, 2006).

Consistent with these associations, agreeableness has reliable correlations with academic performance in primary education, although there is reason to think that this may be partly due to methodological issues associated with self-ratings among younger children (Poropat, 2014a). When agreeableness is rated by someone other than the student, reliable but modest correlations are found (Poropat, 2014a,b), suggesting that agreeableness has persistent but limited impact on educational outcomes.

Emotional Stability

Emotional stability is often referred to by the label for its opposite pole, namely *neuroticism*, a close correlate of the component of temperament called negative affectivity (De Pauw, 2012; Rothbart, 2007). Negative affectivity interferes with learning by prompting task interruption and goal-blocking in response to distress (Rothbart, 2007). More emotionally stable people have weaker reactions to negative stimuli and hence are less readily discouraged, less distractible, and more confident in their own abilities (Ormel et al., 2013). Consistent with this, more emotionally stable students are less anxious and pay less attention to errors, which facilitates learning from errors (Zhao, 2011). This appears to be partly due to the ability of emotionally stable students to switch

focus away anxiety-prompting information, thereby reducing the degree to which they are distracted by ruminative thoughts that actively interfere with learning (Kircanski et al., 2008). Likewise, students who are higher on emotional stability are more able to stay focused on learning activities such as homework, and have better academic outcomes as a consequence (Lubbers et al., 2010).

The consequences of emotional stability extend to motivation and involvement in learning and education. Emotional stability is negatively correlated with discouragement, withdrawing from studies, or general avoidance motivations in education (Komarraju and Karau, 2005; Payne et al., 2007). Unlike agreeableness, emotional stability is negatively correlated with attention to extrinsic demands, such as those imposed by educators (Clark and Schroth, 2010; Komarraju et al., 2009), and is negatively correlated with motivation to learn (Zhao, 2011), possibly due to links with fear of failure. So, the association between emotional stability and academic motivation is complicated.

The association between self-rated emotional stability and academic performance in primary schooling is practically as well as statistically significant, but becomes virtually nonexistent in higher levels of education (Poropat, 2009). However, when other-ratings are used, there is no corresponding decline in this association (Poropat, 2014a,b), suggesting that what changes is the extent to which self-raters accurately report their level of emotional stability, possibly because low levels of emotional stability are socially undesirable.

Extraversion

Extraversion has long been recognized as a major component of individual differences in interpersonal behavior (Wiggins, 1991), and has been linked with aspects of temperament such as surgency and sociability (Mervielde and Asendorpf, 2000), as well as reduced behavioral inhibition and positive affectivity (McCrae and Costa, 1989). Poropat (2009) reported an association between extraversion and academic performance at primary education, but this association disappeared in secondary and tertiary education. Unlike emotional stability, use of self- or other-raters does not affect this pattern. Consequently, the differences in correlations between extraversion and academic performance do not appear to be due to changes in validity of self-ratings.

Poropat (2009) suggested that interaction levels may increase the level of attention that teachers give to extraverted students in primary education, making it easier to identify behavioral examples that warrant better grades. Consistent with this, teachers in primary schools tend to rate shyer, less-extraverted children as lower in intelligence and academic ability (Coplan et al., 2011). It appears that changes in educational assessment methods and reduced levels of interaction with students in secondary and tertiary education explain the reduced correlations with extraversion (Poropat, 2009).

Nonetheless, the impulsivity associated with extraversion can assist educational processes, with students who impulsively provide answers to questions showing greater learning (Tymms and Merrell, 2011), apparently because the simple act of providing an answer increases comprehension (Graesser, 2009). Similarly, extraversion is linked with novelty-seeking (Bernard, 2010), resulting in greater levels of experience and subsequent ability (Dragoni et al., 2011), especially in situations where learners are able to explore their learning environment independently (Orvis et al., 2011). So it appears that extraversion may be useful for learning, but the results are unlikely to affect grades.

Openness

There are strong theoretical arguments for expecting openness to be linked with education (De Raad and Schouwenburg, 1996), and openness has the strongest association with academic performance of any FFM factor apart from conscientiousness (Poropat, 2009), especially when rated by someone other than the student (Poropat, 2014a,b). Much of the reason for the link between openness and educational outcomes appears to be due to motivational effects, with students high on openness having greater curiosity, more interest in developing their ability, enjoying thinking, and generally wanting to improve (Bernard, 2010; Clark and Schroth, 2010; Komarraju and Karau, 2005). Consistent with this, openness is the FFM factor that has the strongest correlations with learning goal-orientation (Payne et al., 2007), and learning goal-orientation appears to mediate the association between openness and learning, and hence educational outcomes (Steinmayr et al., 2011). This focus on learning for its own sake operates independently of formal learning, with students higher on openness demonstrating greater learning in fields independent of their studies (Hambrick et al., 2008).

Students, who are higher on openness also adopt more effective learning strategies, such as greater use of meta-cognitive learning, elaboration on learned information, and effective time management and effort regulation (Bidjerano and Dai, 2007), as well as adopting a deep learning approach to study (Chamorro-Premuzic and Furnham, 2009), all of which reliably affect learning (Graesser, 2009). Taken together, these observations support the conclusion of De Raad and Schouwenburg (1996) that students, who are high on openness appear to reflect the 'ideal' student.

Alternative Personality Models

The advent of the FFM reduced the use of personality measures that fall outside that framework. Although it once was one of the dominant tools for personality assessment, the Eysenckian personality scales (Eysenck and Eysenck, 1975) are rarely used in educational research when compared with FFM measures. Two of the Eysenckian scales, extraversion and neuroticism, correspond closely to scales in the FFM, but although the Eysenckian psychoticism scale has overlaps with conscientiousness it is substantially less strongly correlated with educational outcomes, and further appears to be psychometrically unsound in educational environments (Poropat, 2011a).

The model of personality based upon Reinforcement Sensitivity Theory (RST) was explicitly linked to behavioral learning theory (Corr, 2004). Despite this, much remains to be done to establish RST as a compelling account of learning (Matthews, 2007), and surprisingly little research has been reported that

has tested RST in educational settings, so its relevance to learning and education beyond the psychological laboratory remains to be established.

Moderating Factors

The relationship between personality and educational outcomes has been shown to systematically vary depending on a range of factors. As with correlations with intelligence, correlations of academic performance with self-rated measures of most of the FFM dimensions decline from primary through to tertiary levels (Poropat, 2009). The declines in correlations with intelligence are often attributed to range restriction resulting from reductions in enrollments at higher levels of education, and these range restriction effects seem to also apply to correlations with personality. This makes the lack of significant reduction in correlations with self-rated conscientiousness notable, suggesting that its true relationship with academic performance may actually increase at higher educational levels.

Measurement also has a substantial effect on the size of correlations between personality and academic performance, with other-rated personality typically having significantly larger correlations. In the case of conscientiousness, other-rated measures have correlations with academic performance at both primary (50: Poropat, 2014a) and secondary/tertiary level (38: Poropat, 2014b) that are of similar magnitude to some of the largest effect sizes for influences on educational outcomes, those for class attendance (Credé et al., 2010) and feedback (Hattie and Timperley, 2007). Likewise, openness has substantially higher correlations with academic performance when other-rated, both at primary (43: Poropat, 2014a) and higher educational levels (28: Poropat, 2014b). The reasons for these moderating effects are complex but are likely to include the extent to which different raters use different sets of observations as the basis for their assessments and the extent to which they are differentially affected by desires to present the target of their ratings based on social desirability concerns (Poropat, 2014a,b).

Conclusions

It is a long time since the first systematic study aimed at identifying noncognitive predictors of academic performance, during which personality has mostly been treated as of lesser concern than have cognitive variables, especially intelligence. Recent reviews have clearly demonstrated that this neglect of personality within educational settings has been misplaced, with conscientiousness especially, but also openness and to a lesser extent emotional stability, having important consequences for students' outcomes. These consequences extend beyond the classroom, as has been shown by the now substantial body of research on the consequences of personality for work, health, and social outcomes (Roberts et al., 2007). Careful consideration of the role of personality within educational settings is therefore likely to provide similar benefits to students and society as have earlier efforts inspired by an appreciation of the strengths and limitations of other measures of individual differences.

Abstract

Research on the association between personality and health has a long and notable history. Recently, remarkable advances have been made and thus there is considerably more understanding of why personality is important for health. The development of personality theories has contributed to the improvement in current knowledge and understanding of the association between personality and health, e.g., in terms of health behaviors and stress. In this context, temperament has been shown to be of importance. In the future, more multidisciplinary research is required to better understand the association between personality and health.

Personality has a central role in all-round well-being and health. It is one of the factors, which partly explains variances in health; and to a certain degree, why – even under the same circumstances – some individuals fall ill, whereas others do not. Interest in the connection between personality and health started very early, although coherent personality concepts, which are in line with current personality theories, have only been developed recently. Previously, personality researchers strongly criticized personality concepts, which were used in health psychology. Nowadays a better balance has been reached and the most recent personality theories are used in research on the complicated association between personality and health. Further, sophisticated statistical methods and large follow-up samples are seen as prerequisites for tenable research.

History of the Research

The relationship between personality and health has been investigated for over 2000 years. In Ancient Greece, individuals were already divided into four groups according to predominating bodily humors. Those bodily humors were blood, yellow bile, black bile, and phlegm; and each of these humors was thought to be connected with a certain personality trait or a certain 'temperament,' as the personality traits were called. For instance, an individual whose predominating bodily humor was blood, was believed to have a sanguine temperament that made the person socially active and a seeker of pleasure. In turn, the domination of yellow bile was believed to lead to a choleric temperament that was characterized by high levels of energy and ambition. Further, the predominating bodily humors referred to specific somatic weaknesses too, and consequently, temperaments were thought to be associated with specific illnesses. For example, individuals who were predominated by blood and thus had sanguine temperaments, were seen to be more prone to heart-related problems; whereas individuals with a combination of yellow bile and choleric temperament were thought to be at risk for fatty liver problems.

The current research on the role of personality in all-round health originates in the concept of 'Psychosomatics' as conceived in the 1930s. According to this concept, psychological factors are causative agents for particular illnesses; and certain personalities are predisposed to certain diseases. Personality did not play a role in all conditions but there was a selected category of diseases whose etiology was believed to implicate personality factors. Consequently, personality was not involved in all-round health, but was a special feature in some sensitive 'psychosomatic' individuals. Due to the presumed link between a certain personality and a specific disease, this concept was called the 'Specificity Theory' (Alexander, 1950).

Even in the 1950s and 1960s, this concept provoked growing criticism and it was not widely accepted outside psychoanalytic circles. However, related lines of research have evolved, focusing on the relations between personality, disposition or specific behavior patterns, and the predisposition to specific diseases. A current variation on this specificity theme is the Type A concept, proposed in 1953 to describe people expressing certain behavior traits, such as aggression, impatience, hard-driving effort and hostility; and this pattern of behavior was presumed to be linked to risk for coronary heart disease (Friedman and Rosenman, 1959). This behavior pattern was considered to reflect personality; and during the next years, several very different personality features were named as Type A behavior or were suggested to underlie this behavior pattern.

The Type A concept was rapidly and widely accepted, not because of its solid evidence but because of its practicality. It was an easy way to cope with the complicated concept of personality. It also divided personality into three clear dimensions: attitude, affect, and behavior.

Even though the Type A concept was vague and reflected the specificity theory, it became a landmark concept of modern health psychology in the sense that it raised a wide interest in the role of personality in somatic health. It also brought about a great number of medical and epidemiological studies where psychological factors were included for the first time.

In the 1960s and 1970s, there was a large and growing body of studies on personality and health. Research widened into personality factors to such a degree, that it is not an overstatement to say that personality was associated with onset and progress of all known diseases. Research on psychological risk factors of coronary heart disease, however, maintained its

dominating role. Despite all efforts, however, the results were meager. Personality was shown to be of significance; and always, when personality was assessed in context of health and disease, some associations were found. Nevertheless, the findings were more likely to confirm the existence of personality than demonstrate its role in health. Study designs were mostly correlative and they offered no explanation for the mechanisms through which personality might have effect. In the 1960s and 1970s, searching for this mechanism was not even the focus of the research; demonstrating a correlation between personality and health was seen to be enough.

Long-term, population-based, follow-up studies to examine the development and progress of disease among healthy people and experimental designs to identify mechanisms underlying the association between personality and disease, were typical of the 1980s. Instead of 'psychosomatics,' the term 'behavioral medicine' was used to refer to this branch of science that linked psychology and medicine.

Emotions and Health

Type A Behavior

The Type A behavior pattern was a landmark of modern behavioral medicine. The beginning of the Type A behavior research era was promising and in the well-known longitudinal studies, i.e., the Framingham Study and the Western Collaborative study, an association between Type A behavior and the pathogenesis of coronary heart disease was established (Haynes et al., 1980; Rosenman et al., 1975). Nevertheless, the original finding that the Type A behavior pattern is a risk factor for coronary heart disease could not be replicated. From the vast amount of evidence, it was concluded in 1999 that Type A behavior has only small etiologic relevance for coronary heart disease among healthy adults; and that it is not associated with the prognosis of patients with coronary heart disease (Hemingway and Marmot, 1999).

Nevertheless, instead of the theoretically vague global Type A score, some of its constituent components were shown to be relevant for health, in particular its affective components, i.e., anger and hostility. This development turned the focus of behavioral medicine to the role of affects and emotions in health, i.e., to the very topics which early psychosomatics started from.

Anger and Hostility

From the large amount of Type A behavior-related research, anger and hostility emerged as the most important components affecting health. Up until now, a vast amount of evidence has shown that anger and hostility not only predict physical health but also a range of mental health and social problems. A recent meta-analytic review concluded that anger and hostility are associated with risk of coronary heart disease risk in healthy populations and also in clinical populations with coronary heart disease; the total hazard ratio was estimated to be around 1.2 (Chida and Steptoe, 2009). Currently, it is, however, not clear whether the risks of hostility and anger are equal or whether they differ. Most studies have combined measures of anger and hostility, even though the evidence suggests that there might be important differences between these concepts. In any case, findings on anger and hostility confirmed an old statement that emotional processing is very relevant to health.

Type D Personality

The identification of the role of anger and hostility within the Type A concept contributed to the conceptualization of the Type D personality. Instead of behavior and attitudes, which were emphasized by the Type A concept, negative emotions and low capacity to process emotions characterize the Type D personality. Thus, the Type D personality can be defined as the individual's tendency to experience the combination of negative emotions and social inhibition. Individuals with Type D personality are thus more prone to experience stress and to have poor health behavior-related habits. Early findings suggested that the Type D personality was a clear risk factor for coronary heart disease (Denollet et al., 1996). In a recent review it was concluded that Type D personality was associated with a three-fold increased risk of poor coronary heart disease prognosis (Denollet et al., 2010). Nevertheless, there are also negative reports suggesting that the original estimates might be too high (Smith, 2011).

Alexithymia

Emphasizing a role for emotional processing on health did not start from the identification of Type A behavior but emerged earlier in the 1930s and 1940s, with physicians reporting on patients with severe deficiencies in verbalizing emotions. In the 1970s, Sifneos termed this deficiency as 'alexithymia' (Sifneos, 1977), which means 'no words to emotions.' The term refers to the inability of alexithymic individuals to understand other people's emotional expressions, as well as their inablility to verbalize and interpret their own emotions. In addition to a deficiency of interpreting and verbalizing emotions, alexithymic persons are presumed to lack imagination too, which results in difficulty to benefit from therapy. Alexithymia has been associated with increased mortality, poor physical outcomes, and poor health behavior (Ferguson, 2013).

Toward Comprehensive Personality Concepts

A strong development of personality theories is characteristic of the 1980s and 1990s. Especially in the 1990s, molecular genetics significantly contributed to the development of the concept of personality. More advanced concepts that viewed personality from genetic, neurobiological, and physiological perspectives, also offered better tools to study the link between personality and health through the mechanisms via which personality is likely to have its effect. The focus shifted more toward modern personality theories while pathogenesis, health behavior, and coping with illness and its precursors (e.g., stress) were seen as mechanisms through which personality operates.

Personality Theories

Starting from the 1980s there has been a rapid development in personality research. Nevertheless, consensus about personality

traits has been reached only slowly. Currently, it is widely acknowledged that personality can be seen to consist of a small number of general traits that are formed from a wide number of specific personality dispositions (Digman, 1990). The Five-Factor Model, i.e., the 'Big Five,' is currently the most widely adopted concept to organize these general characteristics into a single model. The Five-Factor Model follows five broad traits: extraversion (e.g., sociability and sensitivity to positive emotions), neuroticism (e.g., proneness to anxiety), conscientiousness (e.g., self-control and allegiance to social norms), agreeableness (e.g., cooperation and trust toward other people), and openness to experience (e.g., curiosity and open-mindedness).

Another widely accepted approach to personality involves differentiation between 'personality' and 'temperament' (Buss, 1991) or 'temperament' and 'character' (Cloninger et al., 1993), in the individual's personality. Temperament, especially, has been shown to be very relevant in the context of health.

Temperament traits are seen as relatively stable behavioral dispositions and tendencies, which are partly heritable and connected to certain biological mechanisms. Possibly due to their neurobiological and physical correlates, temperamental traits have been documented as playing an important role in disease and well-being. At least, Gray's, Buss and Plomin's, and Cloninger's theories can be highlighted in this context.

Gray's (1991) temperament theory postulates two major temperament systems: the Behavioral Approach System (BAS) and the Behavioral Inhibition System (BIS). The BIS is hypothesized to be related to sensitivity to punishment, whereas BAS is seen to be related to sensitivity to reward. Thus, BAS can be seen as the 'GO' or motivation system and BIS as the 'STOP' or alert system. According to Buss (1991), there are three major temperament traits: negative emotionality, activity, and sociability. Negative emotionality is related to arousal and ease in experiencing negative emotions; activity relates to individual differences in physical energy; and sociability is defined as the ability to enjoy other people's company versus being alone. Cloninger's psychobiological theory of temperament includes four temperament dimensions, which are novelty seeking (NS), harm avoidance (HA), reward dependence (RD), and persistence (P) (Cloninger et al., 1993). NS is related to tendency to respond strongly to novelty, whereas HA is defined as tendency to respond intensely to signals of aversive stimuli. RD relates to the tendency to respond strongly to rewards such as social approval, and P is defined as resistance to extinction despite intermittent reinforcement. In addition, Cloninger (1987) suggested that NS is influenced by dopaminergic activity, HA by serotonergic activity, and RD by noradrenergic activity.

Pathogenesis

During the last 20 years, quite a large amount of evidence has been gathered suggesting that personality is related to the pathogenesis of diseases. First findings from the prospective Young Finns Study, which includes 3596 children and adolescents who have been followed from the 1980s up to date, demonstrated that associations between temperament and health are already present at childhood, in that the temperament trait negative emotionality has been found to be associated with the metabolic syndrome in children (Ravaja and Keltikangas-Järvinen, 1995). Later findings from the Young Finns Study have demonstrated that high NS, high RD, and low HA are associated with preclinical atherosclerosis (Hintsanen et al., 2009); and high NS with higher body-mass index (Hintsanen et al., 2012). In addition to evidence from the prospective studies, findings from experimental studies suggest also that there is a connection between temperament and physiological systems. For example BAS-sensitivity has been associated with heart rate reactivity and parasympathetic withdrawal during stressful laboratory tasks (Heponiemi et al., 2004). Temperament trait harm avoidance, which is closely related to the concept of neuroticism, has been associated with higher resting heart rate, which in turn reflects higher for coronary heart disease (CHD) risk (Puttonen et al., 2008).

More recently research has focused on the association between the Five-Factor Model of personality and health. Although associations between almost all of the five personality traits and health were found, conscientiousness could be the most relevant personality trait for health-related outcomes (Bogg and Roberts, 2004). Recent studies using large prospective cohort data from the United Kingdom, the United States, Germany, and Australia have further shown that low conscientiousness is related to obesity (Jokela et al., 2013a), diabetes (Jokela et al., 2013b), and all-cause mortality (Jokela et al., 2013c).

Health Behavior

From the Five-Factor Model personality traits, low conscientiousness has been found to be related to almost all health-risk behaviors, such as smoking and drinking (Bogg and Roberts, 2004). In addition, it has also been hypothesized that individuals who are highly conscientious are more likely to follow social norms and public health recommendations that are related to health behaviors. It is widely acknowledged that most of the associations between temperament or personality traits and somatic problems are at least partially explained by health behaviors. Nevertheless, as demonstrated in the recent study by Jokela et al. (2013c), health behaviors do not fully explain the association between low conscientiousness and mortality. Thus, it seems that personality also affects health through pathways other than health behaviors.

Coping with Illness and Stress

Associations between acccumulated stress and health have been numerously demonstrated. Research has specially focused on work stress such as job strain, job demands, and job control. Numerous studies have shown that personality is related to stress and also to stress perception. Studies using the Young Finns Study prospective data have shown that personality traits, such as high neuroticism, low openness, and low conscientiousness, are associated with high job strain; high neuroticism has also been shown to be associated with high demands and low control (Törnroos et al., 2013). In addition, high negative emotionality and low sociability have been associated with high job strain and imbalance between effort and reward

(Hintsanen et al., 2011). There is also some evidence from experimental studies. For example, Cloninger's temperament trait, high harm avoidance, has been associated with high 'anticipated threat' before a stressful situation and also high 'perceived stress' after the situation (Ravaja et al., 2006).

Other Explanations

Of course, there are also other possible pathways between personality and health. For example personality traits such as high neuroticism, low conscientiousness, and low extraversion have been associated with major depressive disorder (Kotov et al., 2010), which in turn has been shown to predict mortality (Cuijpers and Smit, 2002). Thus, it is possible that individuals first get depressed and after that their physical problems start.

There are also a number of biological processes that can explain the association between personality and health. It is possible that the same genes that contribute to certain personality disposition are also related to certain disease outcomes. Nevertheless, quantitative evidence for these kinds of associations is currently quite scarce. Personality traits are complex traits, which are affected by a vast number of different genes. In addition, it is well-known that genes do not function in isolation but interact with environments. This further adds complexity to the picture.

Conclusion

The evidence suggests that personality plays a major role in explaining why some individuals are more likely to get ill than others. During the last two decades there has been rapid progress in identifying such associations. Nevertheless, there is still much to be done in explaining the association between personality and health. One challenge is to move away from the deterministic single-trait approach that was characteristic of the past and to develop a theoretically solid framework to better understand the link between health and personality. In addition, previous research has been quite disease-focused, and in the future it will be important also to examine the association between personality and good health. Important advances have also been recently achieved in the field of positive psychology.

Future research should especially concentrate on further explaining how personality is associated with the illness process over the life span. It is also important to consider an evolutionary point of view, i.e., personality traits can be seen as evolutionary mechanisms that have different costs and benefits; and thus individual behavior could be adaptive in one environment and maladaptive in another (Ferguson, 2013). It is also important to continue multidisciplinary research, which makes it possible to investigate the role of genes and the environment in the context of personality and health. Taken together, much can be expected from research in the field of personality and health in the future.

Abstract

The success or failure of a marriage is likely to depend in part on the personality (i.e., the enduring traits and characteristics), of the individual spouses. To review research that has explored this idea, this article is organized into three sections. The first section addresses which personality traits have demonstrated consistent associations with marital outcomes. Although over 200 separate personality traits have been examined for their effects on marriage, only neuroticism, or negative affectivity, has demonstrated unique effects across multiple studies. The second section examines the role of similarity and complementarity in accounting for marital outcomes. Although some research supports the beneficial effects of similarity, these effects must be qualified by a number of methodological complexities in the literature. There has been no support for the complementarity hypothesis. The third section describes research on two kinds of intervening processes through which individual personality traits affect marital outcomes. Cumulative continuity suggests that the personality of each spouse shapes the environment of the marriage by giving rise to the stressful circumstances that couples face. Interactional continuity suggests that the personality of each spouse affects the nature of the interpersonal processes occurring within the marriage. Both processes have been demonstrated empirically.

The success or failure of a marriage is likely to depend, at least in part, on the personality of the individual spouses, broadly defined as the set of enduring traits and characteristics that each spouse brings to the relationship. Three questions have motivated most research on the role of personality in marriage. First, what personality traits are most relevant to predicting marital outcomes? Second, does similarity or dissimilarity between partners' personalities affect marital outcomes? Third, through what mechanisms does the personality of each spouse affect the relationship? This article reviews each of these areas of research in turn.

Which Personality Traits Affect Marital Outcomes?

The earliest efforts to predict marital outcomes were guided by the belief that 'a large proportion of incompatible marriages are so because of a predisposition to unhappiness in one or both of the spouses' (Terman, 1938: p. 110). To explore the support for this belief, the first marital researchers conducted two kinds of studies: cross-sectional studies, in which lengthy personality inventories were administered to samples that included happily married and distressed couples, and longitudinal studies, in which personality inventories were administered to engaged couples whose marital quality was assessed several years later. Early marital researchers were more interested in determining whether spouses' personalities accounted for marital outcomes than in identifying which aspects of personality were associated with marital outcomes. Thus, the results of these initial studies were frequently reported in terms of a global personality score rather than divided into specific personality traits. Nevertheless, when Burgess and Wallin (1953), in the first review of this literature, concluded that success and failure in marriage could be predicted by the personalities of each spouse, they noted that personality traits associated with neuroticism (e.g., irritability, moodiness, ill-temper) appeared to be especially predictive. Spouses who reported an enduring tendency to experience negative affect across a variety of contexts seemed to be at greater risk of developing marital distress.

As these results accumulated, the same researchers noticed that other enduring characteristics of the spouses (e.g., childhood family environment, sexual history, demographic variables), were also significant predictors of marital outcomes. Once statistical techniques for conducting multiple regression became widely available, a second wave of research examined the ability of personality traits to account for marital outcomes relative to these other sources of influence. Perhaps the most impressive of these studies is that of Kelly and Conley (1987), who followed a sample of 300 couples for over 40 years. At the initial phase of data collection, engaged partners provided self-reports of their early family environment, attitudes towards marriage, sexual history, and stressful life events. In addition, the researchers contacted five acquaintances of each partner and asked these individuals to rate the personality of the subject, a substantial improvement over the self-report inventories relied on by most prior (and subsequent) studies of personality. When all of these variables were examined at the same time, only the personality ratings emerged as significant predictors of marital stability. Specifically, compared to marriages that remained intact, couples whose marriages dissolved over the course of the study were characterized by higher levels of neuroticism in both spouses and higher levels of impulsivity in husbands.

In the late 1980s, the development of the five-factor model of personality briefly promised to expand the focus of marital research beyond the negative aspects of spouses' personalities. According to this model, the many traits that had been studied in prior research on personality could be adequately summarized by five relatively independent dimensions: neuroticism, impulsivity, extraversion, agreeableness, and conscientiousness. Emerging support for this model lead marital researchers to ask whether dimensions of the 'Big Five' besides neuroticism

and impulsivity may also be associated with marital outcomes. Thus, for example, Kurdek (1993), in a five-year study of newlywed couples, examined the ability of each of the five personality dimensions to predict the quality and stability of marriages over time. This study did find that wives' conscientiousness was weakly but positively associated with the stability of the marriage over five years. However, echoing the results of previous research, far larger effects were obtained for the neuroticism of both spouses. Karney and Bradbury (1995), in a meta-analysis of longitudinal research on personality and marriage, reported that of all of the Big Five personality dimensions, only neuroticism had demonstrated consistent effects on marriage across multiple studies. As the first marital researchers suggested, a spouse's 'predisposition to unhappiness' appears to predict decline and instability in marriage more reliably than other personality traits.

Similarity and Complementarity

As research on personality in marriage has developed, some have argued that the content of each spouse's personality may be less important to understanding marital outcomes than the degree of similarity between spouses' personalities. The assumption of this perspective is that spouses who share similar personalities should experience fewer opportunities for conflict and thus decreased risk of marital dissolution. Bentler and Newcomb (1978) offered some support for this view in a longitudinal study of newlywed couples. Although each spouse's level of extraversion had no independent association with their marital outcomes, the correlation between husbands' and wives' extraversion scores was significantly higher among couples who remained married than among couples who divorced.

Despite the intuitive appeal of this perspective, the accumulation of further support has been limited by a number of difficulties in assessing the effects of similarity in couples. First, the effects of similarity on a given trait are rarely independent of the effects of the trait itself. For example, Kurdek (1993) found that the difference between husbands' and wives' levels of neuroticism was greater in marriages that dissolved than in marriages that remained intact. This finding may support the role of personality similarity in marriage, but it may also result from the fact that differences between spouses are likely to be larger in couples where levels of neuroticism in either partner are higher overall. Estimating the unique effects of similarity between spouses requires that the effects of each spouse's personality be accounted for first. This is a control that has rarely been implemented.

A second difficulty with this kind of research is the fact that, as Kenny and Acitelli (1994) pointed out, 'A couple may appear to be very similar in their responses, yet they may be no more similar than a man and a woman who are totally unacquainted' (p. 419). Because there may be a typical way that most people tend to respond to personality inventories, the personalities of randomly matched people are likely to be similar to some degree. Estimating the unique degree of similarity in a given marriage requires that the 'typical cultural response' be controlled, but again this is a control that has rarely been implemented.

When similarity between spouses has been estimated accurately, support for beneficial effects of similar personalities has been sparse. For example, Russell and Wells (1991) reported that after controlling for the independent effects of each spouse's responses to a personality inventory, the association between marital satisfaction and the differences between spouses' responses was rarely significant. Furthermore, the overall association between spouses' personalities tends to be weak (Buss, 1984), even though spouses tend to be highly similar to each other on many other dimensions. In general, this research suggests that it may be spouses' similarity on those other dimensions, and in particular the degree to which spouses are similar in their values and attitudes, that may be more relevant to account for marital outcomes. With respect to personality, the nature of each spouse's personality appears to be more important than the degree of similarity between them.

In contrast to the similarity perspective, a competing view suggests that it is the degree of complementarity in spouses' personalities that is key to the successful marriage. For example, Winch (1958) argued that spouses select each other to resolve inadequacies in their own characters. Thus, extraverted people should be happiest with introverted partners and domineering people should be happiest with submissive partners. Although this is also an intuitively appealing idea, to date all attempts to obtain empirical support for the complementarity hypothesis have failed.

How Does Personality Affect Marital Outcomes?

Having established that personality traits, especially those associated with neuroticism, predict marital outcomes, the current focus of research on personality and marriage is to explain how this association comes about. Caspi et al. (1989), in their work on the effects of personality throughout the life course, proposed a broad framework that may be applied to understanding this issue. These researchers described two kinds of processes through which personality may affect development throughout the life course. 'Cumulative continuity' refers to all of the ways that individuals' personalities channel them towards certain environments and opportunities. 'Interactional continuity' refers to all of the ways that individuals' personalities affect their behavior towards and cognitions about other people. There is substantial evidence that both of these processes may account for the effects of spouses' personalities on their marriages.

Cumulative Continuity in Marriage

From early childhood, the personality of an individual affects not only the environments selected by the individual but also the opportunities available to the individual. Thus, for example, children who are prone to negative moods may choose career paths that are compatible with their temperament, but their choices may also be restricted by the behavioral consequences of their temperament (e.g., poorer educational attainment, lower professional accomplishment). In this way, individuals' personalities may have cumulative consequences that greatly shape the context of their adult lives. The nature of their adult environments may in turn affect the quality of

individuals' marital relationships. For example, women who experience chronic depression as adolescents tend to marry at a younger age compared to women who do not experience chronic depression (Gotlib, et al., 1998). Age at marriage is associated with risks of divorce, such that people who marry at a younger age are at higher risk for divorce than people who marry later in life. Thus, the stable tendency to experience negative affect in childhood appears to be associated, at least for women, with a life course that is detrimental to marriage.

In a similar vein, the personality characteristics of each spouse may give rise to stressful events and circumstances that impact the relationship. For example, individuals who score higher on measures of neuroticism describe events in their lives as more stressful than individuals scoring lower on such measures (Marco and Suls, 1993). Furthermore, controlling for these reporting effects, higher levels of neuroticism appear to be associated with greater numbers of stressful life events (Poulton and Andrews, 1992). To explain such findings, some researchers have suggested that individuals who are prone to experiencing negative affect frequently generate stressful circumstances that then serve to maintain their negative orientations. As a result of these processes, the marriages of individuals scoring higher in neuroticism may develop in more challenging circumstances than the marriages of less neurotic individuals. Because challenging circumstances, such as unemployment and financial difficulty, have been shown to predict divorce, this may be another route through which the cumulative consequences of each spouse's personality contribute to marital success and failure.

Interactional Continuity in Marriage

In addition to its role in shaping the circumstances of the marriage, personality may also affect interpersonal processes occurring within the marriage. Spouses' expectations for each other, the behaviors they exchange during their interactions, and the way they interpret those behaviors, have all been associated with the stable dispositions of each spouse. Through these mechanisms, the personality of each member of the couple may give rise to self-fulfilling prophecies, such that stable personality traits predict spouses' feelings towards each other and thus lead spouses to act in ways that confirm or enhance those feelings.

Support for these ideas has been especially strong with regard to negative affectivity, that is, neuroticism. For example, spouses who are higher in negative affectivity tend to make less charitable attributions for their partners' negative behaviors. That is, these spouses are more likely to hold their partners responsible for negative behaviors, whereas spouses who are lower in negative affectivity are more likely to excuse their partners for such behaviors (Karney, et al., 1994). Perhaps as a consequence, among newlywed couples, negative affectivity is associated with marital satisfaction, such that spouses who are higher in negative affectivity are likely to evaluate the marriage as a whole more poorly than spouses who are lower in negative affectivity (Karney and Bradbury, 1997). The stable tendency to experience negative affect thus appears to affect spouses' interpretations of the marriage at multiple levels, leading to partners that are perceived as less sensitive and marriages that are perceived as less rewarding.

The effects of each spouse's personality are not merely intrapsychic, however. In established marriages, the negative affectivity of husbands is associated with the marital satisfaction of their wives, such that the wives of husbands who are higher in negative affectivity tend to be less satisfied with the marriage, controlling for their own level of negative affectivity (Karney, et al., 1994). One way that the personality of one spouse may affect the satisfaction of the other is through the effects of personality on the behaviors that spouses exchange during their interactions with each other. Indeed, in established marriages, neuroticism is associated with couples' problem-solving behavior such that more neurotic spouses report feeling more negative than less neurotic spouses immediately after an attempt to resolve a marital problem (Geist and Gilbert, 1996). Furthermore, observational coding of spouses' behavior indicates that more neurotic wives express more negative emotions during conflict discussions. Given that the quality of couples' problem-solving behaviors predicts stability and change in the quality of the marriage over time (Karney and Bradbury, 1997), the link between neuroticism and marital interactions may be one way that the personality of an individual may influence the development of marital quality for a couple.

Future Directions

Although research on the interactional consequences of personality has focused almost exclusively on behavior during marital problem-solving interactions, personality may play an even more prominent role in the way spouses solicit and provide each other with social support. To the extent that personality, and in particular negative affectivity, affects the way spouses treat each other and the nature of the stressful events they encounter, then research on the provision of social support in response to stressful events would be a direction for future research that promises to integrate the cumulative and interactional consequences of personality in marriage.

Editor's Note

A great deal of new research on marriage and personality has appeared since Karney's entry was first published, some of it by the author himself. For a recent statement from the author, see Schoebi et al. (2012).

An important line of research in this area that is not explored in the original is the effects of personality traits on sexual and reproductive behavior. A recent examination of this question is Jokela et al. (2011).

As Karney notes, personality convergence in married couples may result from spousal selection processes (people seek out for marriage partners people who are similar to themselves) or from true convergence (people become more similar in personality traits the longer they are married). The bulk of current research points to 'assortative mating' and not convergence over time as the likeliest explanation. See Humbad et al. (2010); also Le Bon et al. (2013).

Another recent line of inquiry focuses on marital processes (satisfaction, quality of marriages and the like) as the

mechanisms through which personality traits influence health outcomes, for example, coronary arterial disease. For an interesting examination of such possibilities, see Smith et al. (2013).

For an economic analysis of marriage and personality; see Lundberg (2012), which explores the effects of personality traits on the formation and dissolution of domestic partnerships from an economist's perspective. And for an extension of many of the 'marriage and personality' themes to the case of same-sex couples, see the commentary by Cherlin (2013); and the several papers that follow.

Personality and Religion

Abstract

Traditionally, religion has been perceived to shape individuals' personality (traits, but also values and social attitudes). I review here recent research describing the associations between personality and general religiosity, as well as modern spirituality, fundamentalism, and intense religious change. Additionally, longitudinal, genetic, and experimental studies help us to clarify the causal processes. Religion shapes, to some extent, personality but, inversely, genetic and environmental influences also affect the personality–religiosity links. Personality interacts with environmental factors to predict religiosity and with religion to predict relevant psychological outcomes.

For centuries, probably thousands of years, and across all human societies, people vary significantly on whether and to what extent they are religious or nonreligious. In other words, there exists important variability in 'religiousness.' Additionally, people differ in the specific ways (motivations, trajectories, cognitive styles, emotional quality) they are religious or irreligious. In other words, there exists important variability in religious forms. Finally, research in the behavioral and social sciences has shown that believers and nonbelievers, and the different subtypes of each, differ in many aspects of their individual and social lives (cognition, emotions, self-concept, interpersonal relations, social behavior, intergroup relations, family, work, economy, and politics). In other words, religiousness seems to have implications for human psychological functioning at the intraindividual, interpersonal, and group levels (Paloutzian and Park, 2013; Saroglou, 2014).

Personality–Religion Links: Theory

From a personality psychology perspective, it is reasonable to expect that individual differences in religiousness should be followed, to some extent, by personality differences. Religion, that is, beliefs, emotions and rituals, norms, and community, and their related positive or negative attitudes (religiousness), should influence the typical way people think, feel, and behave, that is, their personality. However, given that the basic 'deep' personality traits, also called 'first-level' personality, are mostly stable and enduring, as they are heavily dependent on genetic influences, biology, and temperament, religion's influence on personality can more easily be conceived for characteristics that are at the 'surface' level, also called 'second-' and 'third-level' of personality. These latter characteristics (e.g., social attitudes, identity, self-concept, values, meaning, and ultimate concerns) are more culturally sensitive and malleable and emerge later in life.

However, the opposite causal direction from personality to religiousness is equally if not even more plausible. People with certain basic personality traits, that is, personality predispositions, may be more or less likely to be interested and invest in religious beliefs, practices, and groups, because the latter may either correspond or not to their personality. Unbelievable but true, 'blind' observers are capable of guessing the religiosity of others based only on photographs of their face (Naumann et al., 2009). This causal direction may be direct, from personality to religiousness, or more complex. For instance, individual differences on both personality and religiousness may result from common underlying factors such as common genetic and environmental influences. Alternatively, religiousness, like social attitudes, value hierarchies, and political orientation, may be one of many other narrow characteristics, cultural adaptations of some broader personality predispositions, the latter importantly interacting with specific contextual and social factors (e.g., salience of religion during socialization or key life events).

Note that most scholars in the area of personality and religion agree that religiousness is a sui generis construct of individual differences that is closer, because of its ideological and moral components, but not reducible to values and social attitudes rather than to personality traits (e.g., Ashton, 2013; but see Piedmont, 1999, for an alternative view of spirituality as a basic personality dimension). Basic personality traits are transsituational, importantly heritable, enduring, and descriptive, whereas religiosity, values, and social attitudes are domain-specific, importantly subject to environmental influences, malleable, and rather normative. Empirical studies confirm stronger associations of religiousness with value hierarchies and relevant social attitudes than with personality traits (Roccas et al., 2002; Saroglou and Muñoz-García, 2008).

Research Trends

The study of the personality characteristics of believers, nonbelievers, and their different subtypes has been constant for many decades in the research at the intersection of personality psychology and psychology of religion. That research has often relied on self-reported measures for both personality and religiousness and has been carried out predominantly among Westerners of Christian tradition. Nevertheless, that research has included most of the different theories and models of personality of the last 50 years.

Since the late 90s, research on religion and personality has intensified. This research has increasingly used the five-factor model (FFM) of personality whose strengths, among others, are a structure with relative cultural universality and the capacity to

encompass and integrate into five major dimensions most of the personality traits that were identified in previous personality models. Moreover, recent research has started to investigate religion and personality in non-Christian and non-Western contexts. It has also used meta-analytic techniques, measures of personality other than self-reports (peer-ratings, behavioral measures, or text content analysis), and research designs beyond the simple collection of cross-sectional correlational data (longitudinal studies, laboratory experiments, and multilevel analyses of international data).

Personality–Religion Links: Empirical Evidence

After a short presentation of the FFM and two alternative modern models of similar structure (taxonomy of many traits under a few broad dimensions) that have been used in recent research on personality and religion, a synthesis of the main findings will be presented.

Major Personality Models and Traits

According to the FFM of personality, people differ from each other by being predisposed to typically think, feel, and behave (1) prosocially or egoistically when interacting interpersonally with others (agreeableness); (2) energetically or not in everyday life and when in group (extraversion); (3) orderly and methodically or without self-control when dealing with thoughts, feelings, and goals (conscientiousness); (4) stressfully or with emotional stability when facing challenges from the external and the internal world (neuroticism); and (5) openly and flexibly or conservatively in front of ideas and experiences marked by novelty, variety, and complexity (openness to experience).

Each of these five broad personality factors encompasses many distinct, lower-level, and thus narrower personality traits (facets) that typically point to two more specific tendencies within each factor. Agreeableness includes prosocial, other-oriented tendencies and social politeness; conscientiousness includes prohibitive and proactive tendencies; neuroticism combines emotional volatility and emotional withdrawal; extraversion points to energy but also to assertiveness; and, finally, openness to experience combines intellectual and strictly experiential openness. Some traditional personality traits are disseminated through their subcomponents into more than one factor within the FFM. For instance, the classic trait of impulsivity has its different components under three FFM factors. Other traits (e.g., humorousness or sexiness) are not necessarily captured by the FFM.

Older than the FFM, but still in use, the three-dimensional personality model of Eysenck includes extraversion and neuroticism, but also psychoticism. The latter is a global dimension that combines the low poles of agreeableness and conscientiousness and also includes impulsivity. However, while the two FFM factors point to the prosocial personality, psychoticism is a broader dimension indicating an antisocial and aggressive personality. Furthermore, HEXACO (Ashton, 2013), a newer personality model than the FFM, maintains the five dimensions overall (with minor changes in subcomponents between some factors), but adds a cross-culturally important sixth factor, that is, honesty/humility.

Personality Traits and Religiosity: Main Links

The vast majority of the more than 100 studies of the last 15–20 years have been carried out among Western believers and nonbelievers of Christian (Protestant and Catholic) tradition, but an increasing number of studies in Muslim, Jewish, and Buddhist religious and cultural contexts seem to extend the main lines of findings to non-Christian and non-Western contexts (see for two meta-analyses: Lodi-Smith and Roberts, 2007; Saroglou, 2010).

Indeed, rather consistently across the many studies, religiosity (intrinsic religiosity, global positive religious attitudes, religious beliefs and practice) first reflects prosocial tendencies when interacting with others: it is related to high agreeableness, usually to most of its facets except often modesty, and social warmth, a facet belonging – though marginally – to the extraversion factor. Second, religiosity implies high orderliness, methodicalness, and a tendency for self-control: it is associated with high conscientiousness, in its both inhibitive and proactive aspects, and low impulsivity, a trait whose subcomponents are located under three factors of the FFM and under psychoticism in the Eysenck's model. Third, religiosity is related to the single facet of (low) openness to values (ideological/moral conservatism) but not necessarily to the other components of the openness to experience factor (Saroglou, 2010; see **Figure 1** for the mean effect sizes). In line with the above, across the many dozens of studies that have used Eysenck's model, religiousness is typically associated with low psychoticism, the dimension of antisocial personality defined by coldness and distance in interpersonal relationships and high impulsivity (Francis and Penny, 2014; Lodi-Smith and Roberts, 2007). Finally, also in line with the above, studies on religion and the HEXACO personality traits confirm that religiosity also reflects honesty/humility, a factor

Figure 1 Mean effect sizes (weighted mean correlation coefficients), depicted in bars, of the associations of personality factors with religiosity, spirituality, and fundamentalism. that is partly a blend of agreeableness and conscientiousness (Ashton, 2013).

The above findings indicate that a major underlying tendency of a religious personality is stability, in terms of both social harmony and internal self-control. Indeed, agreeableness and conscientiousness are known to constitute a higher-order factor denoting personal and interpersonal stability. Beyond these personality traits, religiosity is unrelated overall to the core aspects of extraversion (energy), neuroticism (negative emotionality), and experiential and intellectual openness. In other words, religiosity is overall orthogonal with respect to the traits that constitute the second higher-order factor of personality denoting plasticity and growth. These three personality traits are connected with religiosity only in some contexts, for some people, and for specific forms of religiousness (see a later section).

Robustness and Implications of the Links

Beyond occasional exceptions of studies with null findings, more than a hundred studies to date suggest that the above personality 'profile' of religious people may imply some universality. This profile is present in a large number of countries from different continents, across the major religions, different age groups, both genders, and seemingly various cohorts from the last 70 years. More importantly, ratings by peers (parents, teachers, siblings, colleagues, and 'blind' observers), behavioral studies (see a next section), text content analyses, and studies that have controlled for social desirability confirm that although the later may inflate the size of the associations, the religious personality 'profile' is not a simple artifact of social desirability (Saroglou, 2010).

Personality Differences beyond Traits

Moreover, studies that measure second- and third-level personality constructs (e.g., values, social attitudes, identity), which are known to adapt the basic personality traits of the first level (the big five factors) in specific life domains, typically confirm the above main lines of findings. Religious people typically tend to attribute (1) high importance to values denoting conservation (tradition and conformity) instead of openness to change (self-direction); (2) high value to self-transcendence in relationships with proximal others (benevolence, compassion, honesty, but not necessarily universalism); and (3) low importance to values that oppose self-restraint and self-control (hedonism, and to some extent, stimulation) (Saroglou, 2014). Similarly, religious adolescents and young adults prefer identity styles/statuses that emphasize engagement, possibly but not necessarily after exploration, that is, achievement or foreclosure (Saroglou, 2012, for review). Along the same line, studies have shown moderate links of general religiosity (and strong links of fundamentalism) with conservatism (political, ideological, and moral, but not necessarily economic) and authoritarianism (Paloutzian and Park, 2013; Saroglou, 2014), but overall no relation with social dominance (e.g., Hirsh et al., 2013). These social attitudes are known to reflect low openness to experience, but whereas authoritarianism and conservatism additionally relate to high conscientiousness, social dominance additionally reflects low agreeableness.

Cognitive Preferences

The personality characteristics of religiosity tend to translate into specific patterns and preferences in cognition, emotions, and behavior. For instance, studies among nonbelievers and believers socialized as Catholics and Protestants in Europe and the United States show a typical association between religiosity and, more strongly, fundamentalism, with the epistemic need for closure, and in particular with order and predictability – not necessarily closed-mindedness or an urgency to make decisions (e.g., Brandt and Reyna, 2010). This means that, although religiosity does not necessarily reflect simplistic thinking or dogmatism in beliefs and an indifference to opposite beliefs, it is marked by the need for order and structure in the inner world and thus the need for answers, as opposed to keeping existential and other questions open. Similarly, several studies across different countries and religions confirm that religious people tend to endorse just-world beliefs (like 'everybody gets what s/he deserves') and are prone to system justification.

Stereotypes and Meta-Stereotypes

Believers and nonbelievers hold reciprocal stereotypes (what ones think about others) and meta-stereotypes (what ones believe others think about them) in line with the findings on the religion-personality links. High versus low prosociality and conservatism, as well as low versus high hedonism seem to be associated with believers versus nonbelievers, respectively.

One may thus suspect that peer-validation and indirect, though proximal constructs, paper-and-pencil validation of religious self-reported personality tendencies may still suffer from various bias such as stereotypes ('s/he is religious, so s/he must be prosocial'), impression management ('I am religious, so I am prosocial'), or spurious accuracy (peers of religious targets, especially if selected by the latter, may just conform to stereotypes when evaluating the target) (see Galen, 2012). However, existing studies provide behavioral confirmation of the religious personality, at least to some extent and within some contexts.

Behavioral Implications

When results are significant, studies confirm that, under specific conditions (e.g., no conflicting principles, no threat of values) and with some limitations (in targets, motivations, and cost), religious people of various religious traditions tend to behave prosocially, showing for instance, nonaggression, generosity, reciprocity, and assistance (Saroglou, 2013). Religious people also tend to show many conscientiousness-related and control of impulsivity-related behaviors, like low tobacco and drug use, sexual infidelity, and crime, and high educational achievement as well as the capacity to delay gratification (McCullough and Carter, 2013). Moreover, an analysis of the European Social Survey data showed that people who chose fields of study and corresponding jobs involving care for others (teaching, education, personal care services, and medical/health services) had the highest mean scores on religiosity. The fields of study where mean religiosity was the lowest were engineering, sciences, mathematics, and computing, domains independent from prosocial concerns. Finally, religious people do not appreciate disparaging jokes regarding vulnerable targets (disabled people) and jokes that transgress social conventions (death- and disgust-related jokes) and also tend to inhibit spontaneous

creation of humor as a response to hypothetical hassles (Saroglou, 2014, for review). These behaviors clearly reflect high agreeableness and/or conscientiousness.

Note that the mean effect sizes of the associations of religiosity with personality traits and related attitudinal and behavioral outcomes are typically small, most often within the range of 0.15–0.25. Nevertheless, when focusing on many subtler personality traits/facets (instead of the broad personality factors), the explained variance of religiosity may increase up to 15–25% (Kandler and Riemann, 2013; Paunonen, 1998); and when adding values to personality traits, the explained variance may reach 17–45% (Roccas et al., 2002; Saroglou and Muñoz-García, 2008). Finally, as far as the behavioral implications of religious personality are concerned, note that it is the interaction between individual differences and situational factors that predict behavior better than either of these factors alone. For instance, across several studies, the religiosity-helping association ranges between 0.22 and 0.45 when the target is proximal or an ingroup member, but is around zero when the target is unknown or perceived to threaten religious values (see **Figure 2**).

Spirituality, Fundamentalism, and Intense Religious Change

Agreeableness and conscientiousness not only accompany general religiosity, but, as shown in many studies, also characterize – possibly in different strengths – specific religious forms. As shown in Saroglou's (2010) meta-analysis, modern spirituality, which may be independent from institutionalized religion, and mature (reflective) forms of religiosity, and also religious fundamentalism, are all associated with high scores on the above two personality factors. However, other personality traits importantly characterize these religious forms. Spirituality, an autonomous and nontraditional form of reference to some kind of transcendence, denotes growth/plasticity, that is, high extraversion and, more importantly, openness to experience. Religious fundamentalists, on the contrary, tend to be aversive to novelty, variety, and complexity: they tend to be low in openness to experience (see **Figure 1** for the mean correlations across studies).

Moreover, people differ in the way they are, become, or remain religious, spiritual, or atheist. An extensive body of research attests that people who have been religiously socialized, especially by parents to whom they have a secure attachment, develop secure working models of self and others (Granqvist et al., 2010). Their adult religiosity tends to be marked by positive emotionality, positive God representations, and the use of positive religious coping. On the contrary, people who have experienced 'dramatic,' intense conversions and people who have joined marginal small-size religious groups often tend to be characterized by an insecure attachment to parents, insecure adult attachment, a high need for closure, and neuroticism-related traits. They tend to use negative religious coping and have a negative God representation. Finally, atheists and deconverts, or at least some subtypes of them (note that research on personality and specific forms of irreligion is only emerging), tend to be high in openness to experience. Nevertheless, an area still open for future investigation is the extent to which dogmatic believers may resemble or differ from dogmatic, militant atheists.

There is some behavioral validation of the personality characteristics of these specific religious forms. Whereas traditional religiosity typically predicts prosociality toward proximal targets but not necessarily unknown targets and certainly not people perceived to threaten values, spirituality, which combines agreeableness with openness to experience, predicts altruism extended to outgroups, thus being universal. On the contrary, fundamentalism combining low openness with some agreeableness typically predicts outgroup prejudice and derogation, an effect partially explained by authoritarianism and the need for closure, but not by social dominance, a non-empathetic orientation (Saroglou, 2013, for review).

Age, Gender, and Culture

In his meta-analysis, Saroglou (2010) also investigated the potential moderating role of age, gender, and culture on the religion-personality traits associations. The associations of religiosity with agreeableness and conscientiousness, although consistently present across three age groups (adolescents, young adults, and adults), were stronger among older adults compared to younger adults. One interpretation is that religious personality becomes more 'personal' and intrinsic in adulthood, more strongly reflecting prosocial and order-related motives. Moreover, spirituality was more strongly associated with positive emotionality (high extraversion and low neuroticism) in adult samples relative to younger samples, which can be understood in terms of faith maturity: religious doubt reflects less stress and instability in adulthood than in earlier stages of life.

Women's higher prevalence of religiosity – across religions, especially in beliefs and private practice rather than public practice – may result from gender differences in personality (Francis and Penny, 2014). Women, or individuals of either gender who have a high femininity orientation, are higher in prosociality and orderliness, lower in risk-taking, and higher in

dependability and susceptibility to irrational ideas. Beyond these mean differences on both personality and religiosity, the existing evidence suggests that the associations of religiosity with the big five personality traits are similar for men and women.

Agreeableness and conscientiousness accompanied higher religiosity not only in studies from the United States, Canada, and Europe but also in studies from some other parts of the world – though underrepresented in the meta-analysis. Beyond these similarities, differences in the magnitude of effects were found when comparing the first three cultural zones, all of which have a predominantly Christian tradition. Compared to Europe, in the United States, religiosity reflected higher emotional stability (lower neuroticism), what possibly indicates more positive emotionality of religious expressions in today's American Protestantism compared to Europe, more historically marked by Catholicism's guilt. It also reflected higher agreeableness and no low openness to experience, what could be attributable to a stronger multicultural and multireligious tradition in the United States, comparatively with European countries marked by dominant mono-religious traditions. Finally, evidence from large international data (Gebauer et al., 2014) indicates that the associations of religiousness with agreeableness and conscientiousness (a *communion* orientation) are more pronounced in religious countries (religious people seek to assimilate into the predominant norms of these societies). In more secular societies these associations attenuate, and openness to experience and agency (competence, uniqueness, and ambition) become more important characteristics of religiousness (religious people may seek to be unique from the many secular others). These findings are in line with the idea of a shift, in secular societies, from traditional religiosity to modern spirituality.

Personality, Religion, and Behavior: Causal Processes

As stated earlier, theoretically, both directions of causality are conceivable: religion and religiousness may shape personality, and personality may contribute to individual differences on religiousness. Alternatively, personality and religiousness may both depend on third, common causes, or personality may interact with situational factors, thus influencing religiousness. Finally, religion and personality may interact to predict social behavior. Below, the empirical evidence for the above pathways will be presented.

Religious Influences on Personality

There is weak but not dismissible evidence that religiousness longitudinally predicts personality and personality changes and that religious stimulation affects to some extent personality, at least surface-level personality characteristics.

The maintenance of, or increase in, religious involvement among US adolescents was found to longitudinally predict, across late adolescence and emerging adulthood, commitment – but not exploration – in identity status, that is, an increase in foreclosure and a decrease of moratorium and diffusion (Hardy et al., 2011). Religious values of middle adolescents in Australia predicted an increase in agreeableness and a decrease in psychoticism 2 years later (Huuskes et al., 2013); a similar longitudinal influence of adolescent religiosity on agreeableness in late adulthood was found among US women (Wink et al., 2007).

Moreover, evidence from studies on conversion suggests that conversion has an impact on second- and third-level personality constructs (narrow traits, values, social attitudes, meaning, identity) rather than first-level basic personality traits, which are less changeable and more stable and enduring (Paloutzian and Park, 2013). Finally, a series of laboratory experiments show that implicit or explicit exposure to religious ideas and symbols activates agreeableness- and conscientiousness-related social attitudes, cognitions, and behaviors, such as (ingroup) prosociality, self-control, honesty, submission/conformity (Galen, 2012; Saroglou, 2013, for reviews), and decreased social dominance orientation (Hirsh et al., 2013).

Personality Influences on Religiousness

Longitudinal studies from the United States, Australia, and Belgium indicate that personality has chronological priority and an impact on religiousness (studies by Heaven, McCullough, Wink, and colleagues cited in Saroglou, 2010; see also Duriez et al., 2008). Across these studies, religiousness in late adolescence, adulthood, and late adulthood was predicted by high conscientiousness or low psychoticism, measured when the participants were children or adolescents. In addition, high versus low agreeableness in adolescence predicted respectively an increase versus decrease of religiousness throughout adulthood; and openness to experience in adolescence predicted spirituality in late adulthood. Finally, high versus low exploration in adolescent identity status later influenced, respectively, the symbolic versus literal way one approaches religious ideas.

Therefore, from a five-factor theory perspective, religiosity can be seen as one of many other characteristic adaptations, that is, later in life, and narrower in focus (like identities, values, social attitudes, and ideologies), contextual, and cultural adaptations of early basic personality predispositions – here a combination of agreeableness with conscientiousness and low impulsivity. Of course, there is no direct, mere transformation of personality traits to religiosity: value hierarchies and specific social attitudes, themselves being characteristic adaptations of basic personality traits, are stronger predictors of religiosity; additional individual differences (see below) may complement personality and value influences on later religiosity; and individual differences do not predict religiosity alone, but in addition to or in interaction with environmental factors, in particular religious socialization.

Indeed, in addition to basic personality traits, values, and social attitudes, religiosity is associated with (1) other personality characteristics that are located beyond the five factors such as honesty, conservatism, low sexiness, and low humorousness (Saroglou, 2014, for review), as well as (2) individual differences, beyond personality, that are more cognitive in nature, such as low intelligence (Zuckerman et al., 2013) and holistic and intuitive rather than analytic thinking (Gervais and Norenzayan, 2012).

More importantly, there is substantial evidence that an important, if not the major, predictor of religiosity is parents' attitudes toward religion. Religious socialization in general (mainly parents' influence, but also broader socialization) importantly undermines future religious attitudes. Finally, negative life events and also some self-transcendent positive experiences play a role in amplifying interest and investment in religion and spirituality (Saroglou, 2014, for review). Consequently, an integrative theoretical model that better identifies the role of personality in religiousness is one that puts personality in interaction with global environmental factors and personal life events (see Figure 3). Siblings' differential trajectories with regard to religion is the typical example attesting the influence of individual differences beyond, or in interaction with, environmental influences such as religious or atheist family socialization.

Therefore, people who are agreeable and conscientious, if religiously socialized (family and society's influences), and especially if they had developed a secure attachment to their parents, will tend overall to remain religious because religious ideas, emotions, and norms solidify their prosocial and conscientious tendencies. Religion emphasizes ideals of compassion, social harmony, social cohesion, personal stability, and self-mastery. Even if these people experience religious doubts and no longer believe, for example because of their cognitive and social development, their personality predispositions may prevent them from totally abandoning religion due to their desire to minimize conflict and maintain harmony with their religious families and peers.

Agreeable and conscientious people who are nonreligiously socialized, in principle, would tend to develop attitudes and endorse secular ideologies in favor of secular humanism, social justice, and pro-environmental concerns to express and solidify their personality dispositions and respective values. If however they have experienced insecure attachment to parents or in adulthood, or if they are confronted with significant negative life events, their agreeableness and conscientiousness may make them more predisposed than their nonagreeable and nonconscientious peers to be interested and invest in spirituality and religion in order to (re)-establish personal stability, meaning, trust, and faith to their values.

Beyond the above pathways, people who, in addition to agreeableness and conscientiousness, are also characterized by low openness to experience may turn to conservative and fundamentalism religious forms, whereas those with high openness and extraversion, especially in secular countries, will be more in osmosis with modern forms of spirituality.

Genetic and Environmental Influences on Religiousness

Several genetic studies have confirmed that individual differences in religiosity and specific forms of it, like religious fundamentalism, are due to both environmental (shared and nonshared, i.e., unique) and genetic influences (see also Figure 3). New studies helped to clarify the underlying processes. Genetic influences on religiosity are very small during adolescence; in that age period religiosity is heavily influenced by shared environmental factors, mainly family education and broad religious socialization. However, genetic influences become much more important in early adulthood, probably because young adults gain autonomy from family, allowing more fully for the expression of their genetic predispositions (Button et al., 2011; Koenig et al., 2005, 2008). Across studies, heritability estimates for religiosity range between 2 and 29% in adolescence, but between 27 and 65% in adulthood.

A reasonable hypothesis is that the genetic influences on religiosity can be explained through personality influences or that the links between personality and religiosity are due to common genetic influences. This was confirmed in three recent

Figure 3 Theoretical model describing the genetic and environmental influences on religiousness and the role of personality characteristics: basic traits and other individual differences.

studies. In the first, the relationship between religiousness and antisocial behavior measured among 265 male twin pairs (US) was due to both genetic and shared environmental effects. Altruistic behavior also shared almost all of its genetic influence, but only half of its shared environmental influence, with religiousness (Koenig et al., 2007). In the second study on 993 pairs of twins (US), heritable effects underlying community integration and existential uncertainty strongly overlapped with the heritable influences on religiosity (Lewis and Bates, 2013). In the third study on 394 twin pairs (Germany), the associations between religiosity and personality traits in an older and a younger group (agreeableness and low openness, in both groups; and, additionally, in the younger group, conscientiousness) were entirely attributable to genetic influences in the older group and to genetic influences and shared environmental effects in the younger group (Kandler and Riemann, 2013).

There is also evidence that change in religiosity in late adolescence and young adulthood is mostly genetic in origin, with increased nonshared, unique environmental effects (e.g., personal experiences, significant negative or positive life events); stability is determined by both genes and family (shared) environment (Button et al., 2011; Koenig et al., 2008). Shared environmental effects were found to importantly mediate the parent-offspring correspondence in religiosity, but these decreased with age. On the contrary, the self-peers' (friends and spouse) correspondence on religiosity increased with age and was partly explained by genetic and nonshared environmental effects (Kandler and Riemann, 2013). Finally, there seems to exist a genotype-environment correlation in the personality characteristics of religiosity: parents who are agreeable and less open to values transmit both genetically and environmentally their personality dispositions as well as their religiosity to their offspring (Kandler and Riemann, 2013). Note also that, because of the assortative mating (future spouse-similarity on religiousness), the influence of heritability on offspring religiosity (possibly through personality) may have been underestimated.

Personality–Religion Interaction as Predicting Psychological Outcomes

A final way in which personality is involved in religion is that personality characteristics may interact with religious ideas, emotions, norms, and identities or with individual religiousness, to predict various psychological outcomes at all levels: intraindividual, interpersonal, and social.

Here are some illustrative examples coming from recent experimental studies (Saroglou, 2014, for review). In a series of four studies, priming religious concepts increased accessibility of submission-related thoughts, submissive behavior to the experimenter requesting retaliation, conformity to informational social influence, and deontological nonempathetic moral choices, but only among people who were high in dispositional submissiveness or authoritarianism. Religious priming was also found to increase prosocial behavior but only among participants with DRD4 (dopamine D4 receptor gene) susceptibility. Similarly, the priming of Buddhist concepts among Westerners decreased implicit ethnic prejudice, but only among participants who highly valued universalism. Finally, individuals with avoidant attachment style were found to be reluctant to use the compensatory mechanism of God as a safe haven in response to attachment threats.

From a personality psychology perspective, these findings confirm the idea that personality tendencies better predict relevant behavior in contexts and environments (here those involving religious stimulation) that correspond to, and encourage the expression of, such tendencies. From a psychology of religion perspective, these findings underline the fact that religious beliefs, rituals, norms, and groups do not necessarily have universal psychological potential but often seem to be relevant particularly for individuals with specific personality characteristics.

Conclusion

To conclude, personality is, to some extent and rather at the surface level, shaped by religion. More importantly, a specific pattern of personality dispositions (basic personality traits and corresponding values and social attitudes, as well as specific cognitive styles) influence later attitudes toward, specific forms of, and life span changes relative to, religion. Personality, mostly through genetic influences, in early adulthood 'clarifies' or removes the earlier family effects on religious attitudes, in addition to, and possibly in interaction with, significant life events. Finally, religion's influence on individuals' psychological functioning may also pass through, or interact with, personality characteristics. Search for quality in interpersonal relationships, social harmony and cohesion, and personal order and control, especially in the face of uncertainty, seem to be the key mechanisms beneath the personality-religion links. Motives for growth and plasticity do not seem to be the core business of religious personality, but their strength versus weakness importantly colors various forms and expressions of religion, mainly modern spirituality versus fundamentalism.

Abstract

There is a long-standing and persistent belief that risk-taking is a stable personality trait, often referred to as risk attitude or risk preference. This belief implies that a given individual will take similar risks across a range of situations. The article reviews different definitions of risk attitude that show cross-situational consistency to varying degrees. Additionally, several important person-related and situation-related factors affecting risk-taking and its underlying mechanisms are reviewed, including risk perception, risk–value tradeoffs, affective and deliberative processes, and emotion regulation.

There is a long-standing and persistent belief that risk-taking is a stable personality trait, often referred to as risk attitude or risk preference. The belief implies that a given individual will take similar risks across a range of situations and that some people will be more risk-averse (or more risk-seeking) across situations than others. The article reviews different definitions of risk attitude that show cross-situational consistency to varying degrees and highlights several factors related to individual differences that are known to affect risk-taking. Section 'Domain and Framing Effects on Risk-Taking' shows that risk attitude defined within the expected utility (EU) framework varies greatly across situations as a function of decision content and outcome framing. Section 'Risk-Taking and Risk Perception' describes a more promising conceptualization of risk-taking, within a risk–value framework. It models risk-taking as a function of (1) decision-makers' perception of the riskiness and value or return of different courses of action, and (2) their attitude toward perceived risk (PRA), i.e., their willingness to trade off (perceived) risk for return. Two individuals might differ in their recreational pursuits, for example, either because they assess the relative risks of skydiving, bungee jumping, and playing poker very differently (based on past experience, person A may perceive playing poker to be riskier than skydiving and thus choose to go skydiving out of risk aversion – a negative attitude toward risk, while person B may perceive playing poker as the less risky option and engage in it, also out of risk aversion) or, whether their risk perceptions agree or not, because they have different attitudes toward risk as they see it (with persons C and D agreeing on the greater risk posed by skydiving, but person C being attracted by this risk and thus taking it on, and person D being repelled by it and thus choosing to play poker instead).

When modeled within this framework (as described in the section 'Perceived-Risk Attitude as a Stable Trait'), situational differences in risk-taking turn out to result from differences in the perception of risk in different situations rather than differences in willingness to take on (perceived) risk, thus restoring credibility to the notion of PRA as a stable trait. Individual differences in PRA exist, but are smaller and less systematic than individual and group differences in risk perception (with some notable exceptions, e.g., adolescent risk-taking). While the determinants of risk perception are relatively well known at this point not much is known about the determinants of PRA. As described in the section 'Personality, Risk Perception, and Perceived-Risk Attitude,' personality differences in variables known to be related to risk-taking seem to have their effect often via differences in risk perception. In the section 'Multiple Processes in Risk-Taking: Affect, Deliberation, Cognitive Control' we describe an important factor influencing risk-taking that is related to both situation and person, namely the type of the decision processes involved in the decision, in particular more 'hot' affective–motivational processes versus more 'cold' deliberative processes (Figner et al., 2009; Figner and Weber, 2011; Metcalfe and Mischel, 1999). Affective processes have received growing attention in the last two decades. It has become clear that they can influence risk-taking by different routes, for example, in the form of concrete emotions such as anger, fear, or sadness or by way of more subtle and persistent moods (Loewenstein et al., 2001; Peters et al., 2006). Further, it has been shown that (individual or experimentally induced) differences in the *regulation* of these affective phenomena also influence risky decisions (e.g., Heilman et al., 2010; Panno et al., 2013).

Domain and Framing Effects on Risk-Taking

In the EU framework, the dominant normative model of risky decision-making, the term 'risk-taking' is used to characterize choice patterns. Choice of a sure outcome over a lottery with equal expected value is modeled by a concave utility function and described as risk-averse; choice of the lottery is modeled by a convex utility function and described as risk-seeking. Despite the fact that risk-taking simply describes the curvature of the utility function that is derived from a series of choices, "those who coined the term *risk aversion* had in mind the psychological interpretation that someone who prefers the expected value of a gamble over playing the gamble *does not like to take risks*" (von Winterfeldt and Edwards, 1986: 256). Popular as well as managerial folklore tends to interpret risk-taking as a personality trait.

Bromiley and Curley (1992) review the evidence for risk-taking as a personality trait, i.e., as a preference for risk that is stable across situations, and find it lacking (see also Fox and

Tannenbaum (2011) for a more recent overview coming to a similar conclusion). Risk-taking seems to be influenced jointly by the situation and characteristics of the decision-maker, as well as by the interaction of the two (Figner and Weber, 2011). Decision domains in which the same person often shows different degrees of risk-taking include games of chance/gambling, financial investing, business decisions, health decisions, recreational choices, social choices, and ethical decisions (MacCrimmon and Wehrung, 1986; Blais and Weber, 2006; Weber et al., 2002). Further, even within the same domain, individuals can differ in their risk-taking depending on whether they make the decisions in an affect-charged versus a deliberative state (Figner et al., 2009; Figner and Weber, 2011; Gladwin et al., 2011). Modeling risk-taking within EU theory and defining risk attitude as the curvature of a utility function thus is clearly problematic for the notion of risk attitude as a personality trait. Attempts to restore cross-situational consistency to the construct of risk attitude by factoring differences in marginal value (e.g., the incremental value of an additional dollar or an additional life saved) out of the utility function were not successful (Keller, 1985; Weber and Milliman, 1997).

Prospect theory (Kahneman and Tversky, 1979) generalizes EU by postulating different utility functions for outcomes that are framed as gains as opposed to losses. For moderate to high probabilities, when outcomes are framed as gains, choices tend to be risk-averse; when the same outcomes are framed as losses (relative to a higher reference point), choices tend to be risk-seeking, further complicating the interpretation of risk-taking in the EU sense as a stable trait.

Risk-Taking and Risk Perception

In the risk–value framework, risk-taking is a compromise between greed (value) and fear (risk). Risk–value models in finance equate 'value' with the expected value of a risky option and 'risk' with its variance. Generalized risk–value models allow for a broader range of risk measures. Situational differences such as outcome framing also result in different risk perception (Mellers et al., 1997). As a result, apparent differences in risk-taking may be the result of differences in the perception of the riskiness of the choice options, and not of differences in attitude toward (perceived) risk. Cooper et al. (1988) report, for example, that – contrary to managerial folklore – the characteristic that differentiates entrepreneurs from other managers is not a more positive attitude toward risk, but instead an overly optimistic perception of the risks involved. For an outside observer who perceives risk more realistically, entrepreneurs will thus appear to take great risks. However, when differences in risk perception are factored out, entrepreneurs – just as other managers – demonstrate a preference for tasks that they see as only moderate in risk (Brockhaus, 1982).

Perceived-Risk Attitude as a Stable Trait

PRA is a measure of the degree to which individuals find perceived risk attractive (or unattractive) and therefore will choose alternatives that carry greater (or less) risk, all other things being equal. Weber and Milliman (1997) examined its cross-situational consistency by asking commuters to choose between pairs of trains that had risky arrival times (that depended on making a connection that had a stated probability) and to judge which of the two trains was the riskier one. The two trains in each pair had arrival times with equal expected value but different variance. Some pairs of trains had only positive arrival times (faster or equal to current travel times), others had only negative arrival times (slower or equal to the status quo). There was little consistency in people's risk-taking across the gain and the loss domain when risk-taking was defined in the EU sense. Few commuters had preferences that resulted in utility functions that were either both risk-seeking (convex) or both risk-averse (concave). However, consistency across the two domains was very high when PRAs were compared. The majority of commuters were risk-averse in both domains, i.e., consistently chose the train in a given pair that they had judged to be the less risky of the two.

In another study, MBA students participated in two sessions of an investment game where they had to pick one of six stocks (described by standard financial indicators) in each of 10 investment periods, and had to rate the riskiness of the stocks at different points throughout each session (Weber and Milliman, 1997). In one session, participants lost money in most of the 10 periods, whereas in the other session they mostly made money. Choices were very different across sessions (with more switching between stocks in the failure session), as were the ratings of the riskiness of the six stocks. However, over 80% of investors had the same PRA in both sessions, with three-quarters consistently investing in stocks that they perceived to be less risky and one-quarter consistently investing in stocks that they perceived to be more risky.

In a cross-national study, Weber and Hsee (1998) obtained risk judgments as well as minimum buying prices for risky financial investment options from respondents in the USA, Germany, the People's Republic of China, and Poland. Both risk judgments and buying prices showed significant cross-national differences, with Americans perceiving the most risk and Chinese paying the highest prices. However, after differences in risk perception were taken into consideration, the proportion of individuals who were perceived risk-averse or perceived risk-seeking were not significantly different in the four countries, with the majority again being perceived risk-averse, and only a small percentage in each country being perceived risk-seeking.

Personality, Risk Perception, and Perceived-Risk Attitude

Some psychologists have questioned the assumption of finance models that people will and should strive to minimize risk, arguing instead that people's ideal point for risk or uncertainty could differ, either as a personality difference (Lopes, 1987) or as a situational difference (Weber and Kirsner, 1997). Ideal-point models (Coombs, 1975) assume a person will perceive the riskiness of an alternative as the deviation between the alternative's level of uncertainty or unpredictability and the person's ideal point on the

uncertainty continuum. Perceived risk of an alternative with a high objective level of uncertainty would be high for a person with a low ideal point, but low for a person with a high ideal point. Individual differences in ideal points for risk and uncertainty have been measured by the construct of sensation seeking (Zuckerman, 1979), which seem to have some biological basis (Zuckerman et al., 1988) and vary with age and gender. Bromiley and Curley (1992) reported evidence linking sensation seeking to behavioral correlates that include greater risk-taking, especially in the health/safety and recreational domain. Weber et al. (2002) also reported high positive correlations between sensation seeking and its subscales in several content domains, with especially high correlations between the thrill-and-adventure-seeking subscale and recreational risk-taking and the disinhibition subscale and ethical risk-taking. Consistent with the predictions of ideal-point models, the path by which differences in sensation seeking seem to affect risk-taking appears to be differences in the perceptions of risk, rather than differences in PRA. For example, Weller and Tikir (2011) found both domain-*general* and domain-*specific* relationships between perceived risks and benefits and risk-taking on the one hand and HEXACO personality traits on the other hand: The personality trait emotionality was associated with heightened risk perception while the trait conscientiousness was associated with lower perceived benefits, both in a domain-general manner. In contrast, the trait openness was associated with risk-taking and perceived benefits in the social and recreational domain, while the trait honesty/humility was associated with greater risk-taking in the health/safety and ethical domain. These results show that personality traits can be related to both domain-specific and domain-general aspects of risk-return tradeoffs and risk attitudes.

Multiple Processes in Risk-Taking: Affect, Deliberation, Cognitive Control

Recent decision research has highlighted the role of different types of processes involved in risky decisions. Some risky decisions are made in emotionally charged contexts while other decisions are made in a cold deliberative state and these states can affect individuals' risk-taking levels (Figner and Weber, 2011). Figner, Weber, and colleagues developed a 'hot' affective and a 'cold' deliberative version of a risky choice task (the Columbia Card Task, CCT; Figner et al., 2009; Figner and Weber, 2011) and showed that age and other individual differences are not uniform across these types of risk-taking situations, highlighting both that context and involved processes are crucial to understanding risk-taking and that the assumption of a simple single unitary concept of risk-taking is problematic.

For example, adolescents, compared to adults, showed increased risk-taking levels only in the hot, but not the cold, CCT (Figner et al., 2009). This result points to the crucial role of affective processes as well as the (relative lack of) cognitive control processes in adolescent risk-taking and is consistent with currently popular neurodevelopmental models of adolescent risk-taking. This model explains adolescents' risk-taking tendency as a consequence of a developmentally transient potential for an imbalance between strong (subcortical) bottom-up affective–motivational processes versus still immature (prefrontal) top-down cognitive control processes (Gladwin et al., 2011; Somerville et al., 2010; see also Blakemore and Robbins, 2012; Crone and Dahl, 2012; Ernst and Fudge, 2009; Steinberg, 2010; Reyna and Farley, 2006). Thus, adolescent risk-taking is assumed to originate from an interaction between person (adolescents' potential imbalance between strong active affective–motivational processes and relatively weak cognitive control processes) and situation (only in situations in which substantial affective processes are triggered is increased adolescent risk-taking expected).

Further highlighting the role of contextual characteristics and involved processes, personality traits have been found to show differential associations with 'hot' versus 'cold' risky decisions. As expected, risk-taking levels in the hot, but not the cold CCT, were correlated with the motivational construct 'need-for-arousal' (Figner et al., 2009); this construct is related to Zuckerman's sensation seeking construct which, in a separate study, showed qualitatively the same associations with hot and cold risk-taking as need-for-arousal (Penolazzi et al., 2012). In contrast, risk-taking in the cold CCT are related to individual differences in executive functions such as planning and reasoning (Figner et al., 2009) as well as scores on the I7 scale that measures trait impulsivity (Penolazzi et al., 2012). An advantage of the CCT is that it allows for the decomposition of overt risk-taking levels into underlying processes, namely sensitivity to gain, loss, and probability as well as risk-return tradeoffs, which also show differential associations with personality variables. Individuals' reward responsiveness was correlated with increased gain sensitivity when losses were high in the hot CCT whereas individuals' sensitivity to punishment was related to participants' loss sensitivity in the cold CCT (Penolazzi et al., 2012).

Highlighting that not only affect, but also its *regulation* affects risk-taking, recent work has shown that individual (as well as experimentally induced) differences in the strategies people adopt to regulate emotions while making risky decisions lead to differences in risk-taking. For example, Panno et al. (2013) have shown that habitually increased reliance on cognitive reappraisal as emotion regulation strategy is associated with increased risk-taking levels in the cold CCT, accompanied by a reduced sensitivity to both the magnitude and the probability of a possible loss (see Heilman et al., 2010 for similar risk-taking results using experimentally induced emotion regulation strategies). Finally, clinical phenomena related to affective processes and/or their (relative lack of) regulatory processes have been shown to be related to risk-taking: for example, Di Rago et al. (2012) have shown that anxiety, but not depression, is related to decreased risk-taking (see also Maner et al., 2007; Giorgetta et al., 2012). Taken together, these results highlight the importance of both age-related and other individual differences such as personality traits (which also extend into the domain of clinically relevant phenomena) when investigating risk-taking levels; further, the differential associations with 'hot' versus 'cold' forms of risky decisions underscore the need to take into account the context and type of involved processes and the crucial role of affective processes.

Summary, Caveats, and Future Directions

The current research consensus suggests an interactional model of risk-taking (e.g., Sitkin and Weingart, 1995; Figner and Weber, 2011) in which situational characteristics and person-centered characteristics, as well as their interaction (e.g., in adolescents) jointly influence risk-taking. Situational constraints include the content domain of the risky decision, contextual variables such as outcome framing and aspiration levels (Lopes, 1987), and which psychological processes are involved in making risky decisions. Person-centered characteristics include age, gender, culture, and personality. Often, these variables influence risk-taking by changing people's perception of the riskiness of decision alternatives, rather than by affecting their willingness to take on more or less risk. However, these characteristics, e.g., age, can also interact with situational characteristics such that, e.g., excessive adolescent risk-taking is only likely to occur when affective processes are strongly involved and overwhelm adolescents' still immature cognitive control abilities that otherwise might counteract impulsive risk-taking, as it is usually the case in adults (Figner et al., 2009; Figner and Weber, 2011; Gladwin et al., 2011; Somerville et al., 2010).

Because of the domain specificity of risk-taking, measures of risk attitude that employ choice situations across a range of content domains (e.g., the Choice Dilemmas Questionnaire of Kogan and Wallach, 1964) have little predictive validity. Domain-specific scales of risk-taking that help to diagnose apparent differences in risk-taking into differences in either risk perception and/or PRA have been developed (Blais and Weber, 2006; Weber et al., 2002). Similarly, the involved processes matter, e.g., whether risky decisions are made using mainly deliberative calculus or 'hot' affective processes; tasks that systematically vary the involvement of these processes have been recently developed as well (Figner et al., 2009; Figner and Weber, 2011). Future research will provide additional insights into the complex interactions between personality and situation that have been explored for a range of other traits (Mischel, 1999) with respect to risk-taking. A combination of task analysis and theory about the reasons for risk-taking and its cognitive and emotional constraints should lead to the development of gender-, culture-, and domain-specific risk-taking profiles, that predict level of risk-taking in a situation- and person-contingent fashion.

Personality and Self

Abstract

The article seeks to integrate personality and social psychology in a manner that enriches both, particularly with reference to the self and its processes. It is suggested that the typical approach to personality assessment must somewhat necessarily be assessing variations in people's self-concepts and that the beliefs assessed are likely to be generalized (i.e., not very contextual) in nature. Such generalized views of the self will have predictive value, but also predictive limitations. It is further suggested that social psychological views of how personality traits operate may have considerable merit, although there are several ways in which the personality trait literature counters or at least qualifies assumptions made in the social psychology literature. Overall, the personality–self interface appears to be a particularly generative one in understanding individual differences and how they function.

Personality psychology seeks to describe and potentially understand how people differ from each other. It tends to focus on the trait construct – presumably stable, cross-situational tendencies to be a particular type of person. For example, we might state that Suzy is extraverted and Ann is introverted. If this is true, Suzy should be more talkative, dominant, and gregarious than Ann across a wide variety of contexts or situations. Social *psychology*, in contrast to personality psychology, typically views behavior as more malleable and as a consequence of particular situational factors. From this perspective, it may be a mistake to attribute extraversion to Suzy and introversion to Ann in that both individuals may be relatively extraverted when interacting with friends but relatively introverted when in class (Ross and Nisbett, 1991).

A watershed event for both personality and social psychology was the publication of Mischel's (1968) book on personality and assessment. Mischel concluded that traits are rather modest in their ability to predict behaviors in specific situations, that the trait construct may be flawed for this reason, and that it might be more profitable to understand behavior in terms of its situational elicitors. Such conclusions gave rise to what is termed the *person–situation debate*: Is behavior better predicted by knowing about the person or about the situation? In a classic study of this type, Darley and Batson (1973) found that aspects of the person (e.g., intrinsic religiosity) were nonsignificant predictors of helping a potentially-ill confederate, whereas a manipulated situational factor – available time – had a significant influence. The person–situation debate was a source of considerable friction for many years, but it is now apparent that reconciliation is possible. For example, personality psychologists might improve their predictions by attending to situational context, and individuals may differ in their susceptibility to situational influence (Kenrick and Funder, 1988).

Nonetheless, personality and social psychologists continue to pursue different themes while operating on different premises. It is still true that personality psychologists generally adopt correlational designs, whereas social psychologists generally adopt experimental designs (Kenrick and Funder, 1988). And it is still true that there are questions concerning the malleability of behavior from situation to situation (Mischel, 2009). Of particular pertinence to this article, personality and social psychologists also differ in their preferred individual difference variables: Personality psychologists have embraced the trait construct, whereas social psychologists are much more likely to focus on the self-concept and on self-related motives (e.g., self-enhancement and self-protection), oftentimes in the context of transient experiences. The purpose of this article is to highlight ways in which personality and social psychology can inform each other, especially with respect to the personality–self interface. We start by asking a series of questions.

What Do We Assess When We Assess Personality Traits?

Conceptually, personality traits define the major ways in which people differ from each other. For example, the trait of neuroticism encompasses tendencies toward negative emotional experiences, self-consciousness, and stress-related impulsivity. One could potentially assess personality traits in a number of ways (e.g., clinical observations), but in fact one method predominates. People are asked to characterize themselves in relation to adjectives (e.g., 'nervous') or short phrases (e.g., 'worry a lot') consistent with possessing the trait in question (here, neuroticism). There are good reasons to assess personality traits in this manner, perhaps the most important one being that people have considerable knowledge concerning their thoughts, feelings, and behaviors, knowledge that typically outstrips that available to observers.

In assessing personality traits in this way, though, it must be recognized that we are more or less asking people about their *self-concepts* – that is, how the self is viewed. It should, therefore, not be surprising that there are strong relationships between personality trait assessments and assessments of aspects of the self. This is true, for example, for measures seeking to assess the certainty of the self-concept (Campbell et al., 1996), the extent to which one engages in self-deception (Paulhus and John, 1998), and the extent to which one is

high in self-control (Tangney et al., 2004). Moreover, there are strong relationships between *self-esteem* – whether the person views the self as worthy or unworthy – and personality traits as they are typically assessed. In fact, it is now clear that self-esteem may actually constitute a sort of higher-order glue that pervades all five of the 'Big 5' traits – extraversion, agreeableness, conscientiousness, emotional stability, and openness to experience (e.g., Erdle et al., 2010). We do not wish to suggest that personality assessments are synonymous with self-esteem, but we do wish to highlight the importance of the self-concept to what is captured by self-reports of the Big 5.

What Type of Self-Knowledge Is Assessed by Personality Trait Measures?

There are different levels of personality. McAdams (2012) distinguishes personality traits from life narratives, the latter being more fleshed out, intimate, and closely tied to the ongoing goals of the individual. Mischel and Shoda (1995) contrast personality traits, which are situation-general, from a personality-in-context approach contending that consistency can be better understood in situation-specific ('bottom-up') terms. Robinson and Clore (2002a) contrast assessments of current or recent behaviors and experiences with assessments that ask people to characterize themselves over long time frames such as several months, years, or in general.

What is common to all of these frameworks is the idea that personality traits, as typically assessed, are capturing *generalized beliefs about the self*. The focus is on abstract self-knowledge (McAdams, 2012) and long rather than short time frames (Robinson and Clore, 2002b). Along the latter lines, Robinson and Clore (2002b) asked people to report on their emotions over seven time frames varying from short (e.g., last few hours) to medium (e.g., last few months) to trait (i.e., in general). For time frames shorter than the last few months, longer time frames resulted in longer latencies of judgment, consistent with a retrieve and aggregate reporting strategy – that is, recalling many distinct experiences and averaging across them in one's head. For time frames longer than the last few weeks, response times became faster, suggesting abandonment of a retrieve and aggregate strategy in favor of the consultation of more generalized beliefs about the self. When people report on their emotions in general (or over long time frames), that is, they do not appear to retrieve specific information about their actual emotional experiences in real time. **Figure 1** presents data of this type.

While Robinson and Clore (2002b) focused on the effects of time frame, Schell et al. (1996) focused on the influence of context. Participants in their study were asked to judge the self's traits *in college* versus *in general*. After making a self-judgment in relation to a particular adjective (e.g., helpful), participants had to recall a relevant exemplar behavior that they had engaged in (e.g., the time I helped Lucy move in to her new apartment). A control condition was also used in which people merely defined each trait term as it appeared. Very different findings occurred for the self in college versus in general. For the college self, recall was facilitated, suggesting that people recalled relevant behaviors when making these self-judgments. For the self in general, no such facilitation occurred,

Figure 1 Emotion judgment time as a function of time frame (right now, last few hours, last few days, last few weeks, last few months, last few years, and in general).

suggesting that people made these judgments without recalling any specific information that could support them. Again, it appears that trait judgments (i.e., what one is generally like) are not based on retrieving specific information about what one has done, thought, or felt in a real-world context.

Klein et al. (1996) extended this analysis in a very interesting way. They studied the trait judgments of a woman who had been in a terrible motorcycle accident that produced pronounced retrograde amnesia – that is, the inability to recall particular experiences or events from the past. Despite her inability to recall specific experiences, or specific behaviors that she had engaged in, the woman's trait judgments were reliable and valid. Her conceptualization of her own personality traits agreed strongly with knowledgeable informants, for example. In understanding these findings, Klein et al. (1996) contrasted two memory systems, one episodic (i.e., event specific) and centered in the hippocampus and the other semantic and centered in the frontal cortex. Although this woman's hippocampal memory system was severely compromised, she could nonetheless make reliable and valid trait judgments because doing so involves a frontal memory system responsible for much more general self-views – that is., those not tied to any specific memories, past experiences, or behaviors.

Can Such an Analysis Explain Why Trait Judgments Are So Stable Over Time?

Although personality changes over time to some extent, McCrae and Costa (1994) made the rather convincing case that personality trait stability is the more robust phenomenon. In this research, the authors examined test–retest stability for each of the Big 5 personality traits over periods of 5–10 years. The stability coefficients ranged from 0.6 to 0.8. These stability coefficients do not approach 1, the highest value possible, but they are quite high. Moreover, McCrae and Costa (1994) note that such stability coefficients are necessarily limited by the reliability of the assessment scales, which ranged from 0.7 to 0.9.

Thus, personality traits are almost as stable over time as they are reliable at a given time point, a rather remarkable set of findings. The authors further noted that the stability coefficients did not vary by the trait in question, sex or race, or as a function of whether people thought that their personalities had changed over time or not.

In the preceding section, we made a case for the idea that people retrieve what may be termed *crystalized* (i.e., relatively fixed) self-knowledge when making judgments about their personality traits. This perspective can account for the results of McCrae and Costa (1994). Specifically, if people develop crystalized notions of what the self is like, and if this is the sort of knowledge that people retrieve when making trait self-judgments (Klein et al., 1996), then one would expect a high degree of stability of such self-judgments over time. This perspective can explain other phenomena as well. Eder and Mangelsdorf (1997) report that the trait self-judgments of children are quite a bit less reliable than those of adults, differences that can be ascribed (at least in part) to a lack of crystalized notions of what the self is generally like. Relatedly, Watson (2000) reports that trait emotion reports are more stable over time than state (i.e., more recent or current) reports of emotion, precisely as should be expected on the basis of the idea that trait judgments are differentially made by retrieving crystalized self-knowledge.

McCrae and Costa (1994) note that their analysis is somewhat pessimistic on the idea that psychotherapy could change a person's neuroticism level substantially. We agree with this skepticism on the basis of the idea that psychotherapy would be unlikely to greatly affect crystalized notions concerning the self if they are somewhat fixed, as we have contended. On the other hand, it is certainly possible to alleviate and even eliminate more state-related experiences of anxiety and depression on the basis of psychotherapy. Such points were made by Widiger et al. (1999): Successful psychotherapy does not alter trait levels of neuroticism much if at all, but does reduce state-related experiences of distress to a considerable extent. Thus, and as will be further discussed, trait assessments are not particularly sensitive to the ebb-and-flow of our actual emotions and behaviors.

To What Extent Is Self-Esteem Malleable?

Following the influential statements of early sociologists (e.g., Cooley, 1902), social psychologists often view self-esteem as quite malleable. It should rise and fall by successes and failures, whether in achievement-related or social realms. Contrary to this perspective, when self-esteem is assessed in trait-related terms, it does not exhibit these properties. The test–retest stability of self-esteem is remarkably high over time periods as long as 75 years (Trzesniewski et al., 2003). Moreover, the heritability of self-esteem (i.e., the percentage of variance attributed to genetic factors) is quite comparable to that of the Big 5 personality traits (Neiss et al., 2006). Finally, we know of very few studies that have shown that trait reports of self-esteem can be altered by situational feedback. A personality trait perspective can explain why self-esteem does not possess the malleability that was initially proposed in the social psychology literature.

Can the Present Analysis Help Us Understand Trait–State Relations?

When we assess traits, we assess general, crystalized self-knowledge. By contrast, when we assess states or momentary behaviors, we do not. Therefore, personality traits should somewhat necessarily be imperfect predictors of everyday experiences and behaviors. In the emotion realm, Robinson and Clore (2002a) review evidence for dissociations of this type. For example, women report themselves to be more emotional than men on a number of trait emotionality scales, but when emotionality is assessed in state-related terms, sex differences are far less evident. A particularly compelling study was that of Barrett et al. (1998), who asked men and women to complete an experience-sampling protocol and also report on their trait emotionality. Although women were more emotional on the trait scales, they were not more emotional in their everyday lives. On the basis of findings of this type, Robinson and Clore (2002a) suggested that women believe themselves to be more emotional than men to a much greater extent than is actually the case.

A related question is whether trait self-knowledge can mislead us concerning past experiences that we have had. In speaking to this question, Larsen (1992) had participants complete a trait neuroticism measure, report on somatic symptoms (e.g., fatigue, headache, and nausea) in everyday life, and then recall their overall levels of somatic symptoms during this time period. The trait of neuroticism predicted daily somatic symptoms, but it also biased the recall of such symptoms independent of their actual occurrence. That is, as levels of trait neuroticism increased, people were more likely to recall symptoms as having been more pronounced than they actually had been. More work of this type should be performed. For example, would extraversion (agreeableness) bias the extent to which participants thought that they had engaged in extraverted (agreeable) behavior in daily life? Based on extensions of the Robinson and Clore (2002a) model, such retrospective biases should be evident.

There is further support for the Robinson and Clore (2002a) model. A premise of it is that personality traits, as they are typically assessed, constitute a type of generalized self-knowledge that people can default to when they lack more specific information (e.g., when they are asked to recall experiences they may have forgotten). If so, people who have difficulty ascribing meaning to events as they occur should tend to make judgments that are more trait consistent. In two investigations, abilities to assign meaning to events as they occur were assessed in terms of the speed with which people could assign words to different meaning categories. Fast categorizers can assign meaning quickly, whereas slow categorizers cannot. We predicted that trait–outcome relations would be pronounced among slow categorizers, but potentially absent among fast categorizers. In support of these ideas, Robinson and Oishi (2006) found that the trait of extraversion predicted life satisfaction to a much greater extent for slow categorizers than fast categorizers (see **Figure 2** for such a pattern), and Robinson and Clore (2007) found conceptually identical results for relations between neuroticism and somatic symptom reports (see also Robinson et al., 2006). These results encourage us to think of trait assessments in terms of generalized self-knowledge

Figure 2 Life satisfaction as a function of categorization speed (fast vs slow) and extraversion level (introvert vs extravert).

that can 'contaminate' more state-related judgments among some people.

Are the latter sorts of effects merely about self-reports, though? We would like to suggest that they extend beyond them. In support of this idea, Robinson and Oishi (2006) found that slow extraverts (relative to fast extraverts or introverts) displayed greater happiness in pictures, a finding that cannot be ascribed to merely *self-reporting* greater happiness (see also Robinson and Cervone, 2006). Similar considerations apply to the results of Robinson et al. (2006). Thus, we would like to suggest that some people (e.g., slow categorizers) live lives that are more influenced by their personality traits than others (e.g., fast categorizers), an idea that extends the analysis of Robinson and Clore (2002a).

Are There Limitations to the Trait Assessment Approach?

Following the analysis above, it may be useful to recognize that people are not always very 'traited' in their everyday experiences and behaviors. For example, nearly all people engage in extraverted behavior in some situations, but introverted behavior in others (Fleeson, 2007). In addition, the situations that activate extraverted behavior are likely to differ across individuals (Cervone, 2004). These sorts of considerations have given rise to an alternative perspective on individual difference consistency that views it in terms of if–then situation–behavior profiles (Mischel and Shoda, 1995). The idea is that people are consistent in how they respond to particular situations over time (e.g., Cathy is almost always talkative at home), but not in how they respond to different situations at a given time (e.g., Cathy is rarely talkative at school, though she is at home). The trait approach will miss such nuances.

Another observation worth making is that personality trait measures assess explicit or conscious views of the self. Such views have their limitations in that people may lack awareness concerning some important aspects of the self and its tendencies (Vazire and Wilson, 2012). Supporting this point, there is a long line of research suggesting that motives can often operate implicitly or unconsciously. Implicit measures of motivation do not tend to correlate with explicit measures, yet predict spontaneous and long-term outcomes consistent with possessing the motive in question (e.g., argumentativeness as a function of power motivation: McClelland et al., 1989).

There is another body of work showing that Implicit Association Tests can be used to assess the implicit self-concept. Such assessments are reliable (Schnabel et al., 2006), tend to be only weakly correlated with their explicit (trait) counterparts (Egloff and Schmukle, 2002), and yet predict relevant behavioral outcomes. For example, implicit views of oneself as shy predict global ratings of anxiousness in stressful situations (Schnabel et al., 2006), dysfluent speech (Egloff and Schmukle, 2002), and a variety of other nonverbal indicators of distress in social situations (Back et al., 2009). The trait assessment approach, then, can miss out on some important process-based predictors of relevant outcomes (Robinson and Wilkowski, 2014).

Can Social Cognitive Views of the Self Speak to How Traits Operate?

The trait approach is primarily descriptive – that is, it describes how individuals differ from each other. In understanding how traits function, though, social cognitive views of the self, and particularly its motives, may represent a useful addition to the literature. Paulhus and John (1998) make the case that *self-enhancement* motives (i.e., to view oneself as positively as possible) may account for why people generally characterize themselves in socially desirable terms. Individual differences in operations of a self-enhancement motive have been most convincingly established for the trait of narcissism (Paulhus and Williams, 2002), but can be extended to the traits of the Big 5 (Paulhus and John, 1998).

In addition, people are motivated to confirm existing views of the self – a motive termed *self-verification* (Swann, 1992). This important motive can explain why personality traits are remarkably stable over time (McCrae and Costa, 1994). It can also explain other features of how traits function. For example, people high in the trait of neuroticism often seem to create distress for the self, whether due to their tendencies to appraise events negatively, habitual worry, poor coping choices, or negative interpersonal behaviors (Suls and Martin, 2005). Tamir (2005) has shown that people high in neuroticism will *choose* to worry in some performance contexts and Tamir and Robinson (2004) have shown that negative emotional experiences seem to facilitate affective understanding for neurotic (but not non-neurotic) individuals. At some paradoxical level, then, people high in neuroticism seem to prefer to be distressed – not because it is pleasurable, but because it fits existing conceptions of the self. Such self-verification perspectives and processes should be extended to the other Big 5 traits.

Turning to a different self-related motive, terror-management theory (TMT) posits a *self-transcendence* need (i.e., the need to perceive the self or part of it as symbolically transcending physical death) that compels people to identify with their own cultural beliefs while discriminating against out-group members who do not share such beliefs, among other dependent measures (Solomon et al., 2000). Terror-management processes are typically examined by randomly assigning some people to

write about what would happen with the self's death versus a control topic, a manipulation termed mortality salience (MS). Initial research on TMT examined the effects of MS in normative terms – that is, effects that presumably characterize all people equally (Solomon et al., 2000).

It is increasingly apparent, however, that the effects of MS manipulations can inform our understanding of how personality traits operate. Harmon-Jones et al. (1997) first reported that people low, but not high, in trait self-esteem were more affected by such manipulations, results consistent with the idea that higher levels of self-esteem serve a terror-management function. Indeed, Routledge et al. (2010) observed that MS increased distress and decreased well-being only among individuals low in trait self-esteem. Another body of work has shown that 'creatureliness' (i.e., having bodies that eat, sweat, have sex, and so on) appears to be more threatening as neuroticism levels increase. Under conditions of MS, people high (but not low) in neuroticism seek to avoid activities that remind them of their bodies (e.g., Goldenberg et al., 2006). TMT perspectives of attachment styles (Cox et al., 2008) and personal need for structure (Landau et al., 2004) have also been productive. Such findings are not just informative to the TMT literature, but potentially also to the personality trait literature.

Another body of work has highlighted the value of attending to *self-regulation* processes in understanding the personality trait of agreeableness. Agreeableness is a strong inverse predictor of anger and aggression, but there are several alternative reasons why this might be the case. To disentangle these alternatives, Meier and Robinson (2004) measured the accessibility of hostile thoughts because hostile thoughts are a major contributor to anger and aggression. Agreeable people did not have less accessible hostile thoughts, but such thoughts were less likely to result in anger and aggression at high (relative to low) levels of agreeableness. See **Figure 3** for an idealized pattern of this type. In other words, it appears that agreeable people self-regulate the influence of their hostile thoughts, essentially remaining agreeable despite them.

Subsequent studies have provided direct evidence for agreeable self-regulation. Wilkowski et al. (2006) found that agreeable people shifted spatial attention away from hostile stimuli, whereas disagreeable people did not. Meier et al. (2006) found that agreeable people recruited prosocial thoughts when primed by hostile ones, whereas disagreeable people did not. More recently, Bresin et al. (2012) found that hostile thoughts facilitated motor control among agreeable people, but not disagreeable people, and that this 'agreeable' response to hostile primes predicted lesser anger reactivity in daily life. Other studies have shown that agreeable people (in these studies, in terms of low-trait anger) recruit cognitive control when primed by hostile thoughts (Wilkowski and Robinson, 2008) and pause following their negative evaluations (Robinson et al., 2012). Altogether, the studies converge on the idea that agreeable people possess remarkable self-regulatory mechanisms that can explain why they are less predisposed to anger and aggression. Process-based analyses of this type can be applied to other personality traits as well (Robinson and Wilkowski, 2014).

Conclusions

The interest in behavior and experience is shared by personality and social psychologists, but their favored constructs, methods, and assumptions differ. Despite such differences, these subdisciplines of psychology can inform each other, as this article makes clear. We first suggest that personality traits, as typically assessed, must somewhat necessarily be assessing aspects of the self-concept. The fact that there are five relatively orthogonal dimensions along which self-concepts differ is a contribution to the social psychology literature. There are different levels of self-knowledge, perhaps most clearly articulated in Klein's (e.g., Klein et al., 1996) work. From the perspective of this work, it is apparent that personality traits capture generalized or crystalized beliefs about the self that are independent of particular contexts or time frames. Such assessment methods can explain why trait judgments are so stable over time, a contribution to the personality literature. Although several theorists contend that self-esteem is quite malleable, this appears not to be the case, a contribution to the social psychology literature.

Because personality traits assess generalized self-knowledge, we should expect systematic divergences between trait and state assessments and some divergences of this type (e.g., concerning sex differences in emotionality) were reviewed. Moreover, this perspective on what is assessed by personality traits possesses implications for understanding variability in trait–state or trait–outcome relations across people. In specific terms, and following Robinson and Clore's (2002a) model, it was proposed that traits should be predictive of outcomes or states particularly among people less capable of assigning meaning to events as they occur. Some evidence of this type was reviewed, work that highlights a role for cognitive processes in understanding trait–state relationships. The final two sections suggested potential limitations to the trait assessment approach and called for complementing social-cognitive analyses.

In sum, we wish to emphasize the following points. The typical approach to assessing personality traits must somewhat

necessarily be assessing what people think of themselves. That such assessments are useful in outcome prediction may be understood in terms of self-related processes to a greater extent than previously recognized. If so, self-related perspectives of personality traits possess considerable merit in understanding how they operate.

Personality and Values at Work

Abstract

Individuals' personality and values have important implications in the workplace and can be used in conjunction with other metrics to predict outcomes relevant to organizations, such as job performance. Instruments for assessing personality and values can thus be potent tools in hiring and promotion processes. In this article, we review the history of research surrounding personality and values in the workplace, discuss recent contributions to the literature, and identify existing issues and areas of future research.

Two decades ago, noted organizational scholar Adrian Furnham lamented that "organizational behavior theorists and management scientists have neglected to examine individual differences in any systematic way … while personality theorists have been eager to examine clinical, educational, medical and social correlates of individual differences/personality dimensions, they have consistently ignored occupational/organizational correlates" (Furnham, 1992: p. 2). A surge of research over the last 20 years has addressed this oversight. Hundreds of empirical studies and dozens of meta-analyses have explored relationships between individual differences, such as personality and values, and a vast array of important workplace attitudes and behaviors.

In this article, we explore the roles of personality and values in the workplace, their impact on work outcomes, and implications concerning organizational policies, practices, and systems. We define personality as the relatively enduring structures and propensities within individuals that explain their generalized affective, cognitive, and behavioral tendencies (Hogan et al., 1996). Values reflect preferences for certain situations, objects, goals, or behaviors over others (Schwartz, 1999). A subtle yet important distinction between personality and values is that the former describes one's social reputation, whereas the latter describes one's preferences. In the following sections, we review the literature regarding these two individual difference variables, focusing on empirical findings, recent developments in paradigmatic focus, and practical implications. We also highlight existing questions, emerging issues, and areas in need of future research.

Personality

The History of Personality in the Workplace

The above-mentioned dearth of empirical research relating personality to workplace outcomes through the late 1980s could be attributed to several causes. Critics of personality (with roots traced to behavioralism) argued that individual behavior was a function of the situation rather than any internal forces, that researchers overestimated behavioral consistency, and that relationships between personality traits and behaviors were illusory in nature. In addition, reviews of what little empirical evidence existed offered rather disappointing conclusions. For instance, Guion and Gottier (1965) analyzed the literature regarding the use of personality tests in organizational contexts and concluded, "It is difficult in the face of this summary to advocate, with a clear conscience, the use of personality measures in most situations as a basis for making employment decisions about people" (p. 160).

At least three factors have accounted for increased optimism and research regarding the role of personality in the workplace. First, longitudinal studies revealing the stability of personality over time and the impressive relationships between personality and outcomes measured years apart put to rest several criticisms regarding the illusory nature of this construct. For instance, Finn (1986) found considerable stability in personality traits across a 30-year span. Moreover, Judge et al. (1999) found childhood measures of personality to predict career success assessed 50 years later.

Second, a taxonomy of personality traits – referred to as the 'Big Five' or 'Five Factor Model' for its aggregation of personality into five broad trait domains (see **Table 1**) – gained widespread acceptance in the field of personality psychology (*see* Five Factor Model of Personality, Facets of). Before the introduction of the Big Five to the organizational sciences, the accumulation of

Table 1 The Big Five personality traits

Personality trait	*Basis*	*Facets*
Conscientiousness	Need for achievement and commitment to work	Competence; order; dutifulness; achievement striving; self-discipline; deliberation
Agreeableness	Quality of social interaction	Trust; straightforwardness; altruism; compliance; modesty; tendermindedness
Emotional stability	Propensity toward negative emotions and anxiety	Anxiety; hostility; depression; self-consciousness; impulsiveness; vulnerability to stress
Openness to experience	Appreciation for art, emotion, and new things	Fantasy; aesthetics; feelings; actions; ideas; values
Extroversion	Preferred quantity of social interaction	Warmth; gregariousness; assertiveness; activity; excitement-seeking; positive emotion

personality trait findings was hampered by the vast number of different traits being investigated. Consensus regarding the nomenclature and hierarchical organization of traits allowed researchers to better aggregate and communicate empirical findings. This also led to a shift of focus from very narrow, specific personality traits optimized for predicting narrow behavioral facets to broad personality domains seemingly better suited for predicting broad, complex work outcomes like job performance and turnover.

Finally, accompanying the emergence of the Big Five taxonomy was the introduction of meta-analytic techniques to the organizational literature (*see* Systematic Reviewing and Meta-Analysis). By organizing the vast array of personality traits into broad factors, quantitatively integrating findings, and accounting for study artifacts such as sampling and measurement errors, researchers attained stable patterns of relationships undiscovered by early narrative literature reviews. The following section highlights relationships between Big Five personality traits and important workplace attitudes and behaviors uncovered by meta-analytic reviews conducted in the time since the publication of the Encyclopedia's previous edition.

The Big Five Personality Traits in the Workplace

In terms of all Big Five traits, perhaps none is as relevant to workplace criteria as conscientiousness. Reflecting an individual's industriousness and orderliness, this trait is the strongest Big Five predictor of overall job performance, and the importance of conscientiousness generalizes across cultures, occupations, and performance criteria (Barrick et al., 2001). Conscientious employees are more likely to engage in positive citizenship behaviors by going above and beyond their job roles to help out their employer and fellow coworkers (Chiaburu et al., 2011). They are also less likely to engage in deviant behaviors at work, such as theft and property damage (Berry et al., 2007); be involved in workplace accidents (Clarke and Robertson, 2008); and voluntarily leave their jobs (Zimmerman, 2008). Conscientiousness has been shown to be an important trait in the context of leadership, though it more strongly predicts the likelihood that an individual emerges into a leadership position than the likelihood that an individual is effective in that role (Judge et al., 2002a).

Emotional stability – or the absence of neuroticism – is generally regarded as the second most important personality trait predictor of workplace outcomes. Like conscientiousness, this trait predicts overall job performance across occupations, though to a slightly lower degree (Barrick et al., 2001). Emotional stability is also negatively related to workplace deviance, accidents, and turnover. Furthermore, emotionally stable individuals are more likely to emerge into leadership positions and tend to be more effective in these roles (Judge et al., 2002a). The importance of the remaining Big Five traits tends to be much more dependent on the type of job and/or workplace criterion. For instance, extroversion is a valuable predictor of success in managerial jobs, agreeableness in jobs that require interpersonal interactions, and openness in contexts requiring training and learning as opposed to routine task accomplishment (Barrick et al., 2001; Mount et al., 1998).

Accounting for the above-mentioned relationships with workplace behaviors, personality impacts several critical work attitudes and processes. Conscientiousness, emotional stability, and extroversion all positively predict overall job satisfaction (Judge et al., 2002b), and individuals with these traits also tend to be more motivated in the workplace (Judge and Ilies, 2002), as well as more resilient in the face of stress (Alarcon et al., 2009). Likewise, team performance is affected by member personalities, though the optimal configurations depend on the particular trait (Bell, 2007). For agreeableness, team performance is heavily influenced by the team's least agreeable member, as one 'bad apple' can spoil the bunch. Concerning extroversion, it may be desirable to have a heterogeneous mix of this trait so that introverted members can balance out the extroverts and vice versa (Neuman et al., 1999). However, for conscientiousness, too much heterogeneity can be a suboptimal combination (Barrick et al., 1998).

In sum, recent meta-analytic investigations have uncovered meaningful relationships between personality and a vast array of important workplace attitudes and behaviors. However, whether and how organizational decision makers can best capture and utilize personality information has been the subject of intense scrutiny and several critical questions remain. Below, we explore existing debates and future research streams.

Current Concerns and Future Research

A poll conducted by the Society for Human Resource Management in 2011 revealed that less than 20% of organizations use personality tests for hiring or promotion decisions (SHRM, 2011). Despite considerable evidence in support of statistically significant relationships between personality traits and workplace outcomes, some researchers and practitioners question whether the magnitudes of effects are practically meaningful and strong enough to justify their use in personnel selection contexts. Moreover, some scholars argue that the effect sizes of personality traits are just as disappointingly low as they were in Guion and Gottier's review, and that even with methodological improvements, individual personality traits only account for a very small portion of overall job performance.

In response, advocates of personality testing point out that meta-analytic investigations may offer conservative predictive validity estimates since they often aggregate empirical research without any theoretical reasoning to suspect that a given personality trait would be predictive in a certain context. When only specific and theoretically justified relationships between personality and performance are meta-analyzed, personality traits tend to have much greater explanatory power (Hogan and Holland, 2003). In addition, organizations rarely assess just one personality trait in testing contexts, so the composite validities of multiple traits may be a more appropriate metric. Research shows that simultaneous analysis of all Big Five traits greatly improves the prediction of job-related outcomes, making personality about as predictive as other important job-selection constructs, such as cognitive ability and job experience (Barrick and Mount, 2005). In addition, the Big Five traits generally do not differ systematically across racial and ethnic groups, which can help promote hiring practices that foster a diverse workforce (Barrick and Mount, 2005).

A second obstacle to the widespread acceptance of personality testing in the workplace is the issue of responder faking. In high-stakes contexts, where hiring or promotion decisions depend on the outcome of personality tests, applicants may be especially motivated to distort their responses in order to appear more attractive to employers. Organizations have several options to combat faking. First, they might attempt to reduce applicants' desire to fake by requiring applicants to elaborate on their responses (e.g., by providing specific examples of situations where they exhibited a trait) or simply by warning applicants not to fake. Second, organizations might reduce applicants' ability to fake. Forced-choice inventories require applicants to select from equally desirable options (e.g., "do you describe yourself as ambitious or helpful?"), making it difficult for test-takers to ascertain the 'correct' response. In addition, conditional reasoning tests require applicants to justify their actions in certain situations; personality trait scores are inferred based on the applicants' underlying reasoning processes. Finally, techniques exist to identify individuals who fake. One such technique relies on 'lie scales' – items included in the assessments that are designed to measure the likelihood that respondents are purposefully distorting responses on the actual personality tests. More advanced techniques involve measuring individual item's response times or tracking test-taker's eye movements, and are currently being developed with preliminary success (van Hooft and Born, 2012).

Some researchers contend that the issue of faking is much ado about nothing, as the opportunity to fake does not necessarily make it impossible to extract meaningful information from personality test scores. For starters, they argue that even though faking is possible, the actual prevalence is lower than presumed (Hogan et al., 2007). Moreover, the occurrence of faking alone is not necessarily harmful to personality test validity. For instance, if all applicants fake (to a similar degree), then the rank-ordering of applicants by personality test scores will remain consistent even though response distortion occurs. Alternatively, if different people fake to a different extent, but the factors that impact the magnitude and direction of faking are themselves organizationally desirable, then response distortion may not necessarily invalidate assessment results. For instance, motivated individuals may be more likely to engage in impression management and intelligent individuals may be better at distorting responses in the organizationally desired direction. In regard to these issues, empirical evidence shows that the predictive validity of the personality tests remains substantial despite the threat of faking (Ones et al., 2007).

The current state of research has experienced a shift in focus from examining if personality is worthwhile to examining how to maximize its predictive power. One stream of research is revisiting the notion that the Big Five represents the optimal operationalization of personality traits. Recent meta-analytic evidence suggests that assessing personality at a level of specificity narrower than the Big Five might increase criterion-related validity (Judge et al., 2013). In addition, several broader, compound traits – integrity, proactive personality, core self-evaluations – increase predictive validity in certain contexts (Ones et al., 2005). Then there are other traits, for example, Machiavellianism and Narcissism, that do not quite fit within the construct domain of the Big Five and yet deserve increased empirical attention.

A second approach to increasing the effectiveness of personality testing involves contextualizing such assessments. Respondents are asked to rate not their general or global personality but their personality specifically in the workplace. The evidence to date suggests that providing respondents with a frame of reference increases both the reliability and predictive validity of personality assessments (Lievens et al., 2008).

Finally, recognizing the limitations of self-report assessments of personality (such as faking or a lack of self-awareness), researchers continue to explore alternative means of collecting applicant personality information. Some fruitful avenues of research entail acquiring personality ratings from coworkers, spouses, and independent raters. Moreover, independent raters might evaluate personality from information collected via observation, interviews, application materials, or even publicly available online social profiles. Oh et al. (2011) meta-analyzed the predictive validity of observer ratings of personality and found that they were between 30 and 340% higher than self-ratings, depending on the traits being rated.

Summarizing the literature, Judge et al. (2008: p. 1983) remarked: "From the vantage point of today, that personality has shown itself relevant to individual attitudes and behaviors as well as team and organizational functioning seems an incontrovertible statement." Despite the progress made since publication of this Encyclopedia's previous issue, additional work is needed to understand the dynamic processes through which personality shapes workplace attitudes and behaviors and vice versa. In addition, future research will continue to refine and innovate assessment techniques to overcome current limitations and maximize their predictive validity.

Values

Values are "conceptions of the desirable that guide the way social actors (e.g., organisational leaders, policy-makers, individual persons) select actions, evaluate people and events, and explain their actions and evaluations" (Schwartz, 1999: p. 24–25). Like personality, values shape how people perceive and respond to the external environment. However, two features distinguish values from personality: (1) personality reflects behavioral reputations, whereas values describe preferences and intentions; and (2) personality traits vary in terms of how much of a particular characteristic is present/absent in an individual's reputation, whereas values vary in terms of the relative importance of a given preference over other values (Bilsky and Schwartz, 1994). Like early personality trait research, the accumulation of knowledge regarding the importance of work values is hampered by the multitude of values and value typologies being examined. In the following section, we outline two distinct streams of research. The first explores the role of employee–organization value congruence – that is, the match between the values employees consider most important and those that are able to be satisfied by the organization. The second explores the role of national culture on shaping the values of a workforce.

Value Congruence

A well-established maxim in the organizational literature is that employees are most engaged in their work when there is a sense of compatibility between their values and the work environment. Whether conceptualized as congruence with one's job, work unit, supervisor, or organization, value congruence has been meta-analytically linked to outcomes such as job satisfaction, organizational commitment, organizational identification, performance, and turnover (Kristof-Brown et al., 2005). More recently, scholars have begun integrating parallel streams of congruence research. For instance, one paradigm conceptualizes value congruence in terms of complementary fit, where the organization provides what the individual most values. A second paradigm conceptualizes congruence in terms of supplementary fit, where the employee's values are consistent with those of the organization (or existing organizational members). Empirical evidence suggests that both conceptualizations of congruence contribute independently – and with similar magnitudes – to work outcomes (Cable and Edwards, 2004).

A second recent advancement within this literature is a deeper examination of the impact of misfit. Whereas traditional theoretical and empirical approaches treated all types of misfit as equally suboptimal, recent developments suggest more complex models. Relying on polynomial regression and surface plot analysis methodologies, several scholars have uncovered asymmetrical misfit effects. An oversupply of particular values – getting more than one might desire – is less detrimental than an undersupply and, in many cases, leads to more positive outcomes than exact correspondence between values (Kristof-Brown and Guay, 2011).

Cultural Values

Whereas personality research is predominately concerned with individual differences, there is an extensive and growing body of literature on the impact of national culture on the values of employee populations. Broadly speaking, cultural values shape how people prefer to manage and be managed, as well as their attitudes toward work. Several common frameworks exist for understanding cultural values. Schwartz's (1999) theory of cultural values suggests that all cultures are confronted with three social issues and the institutions developed to resolve these issues impact member values. The first issue is the need to define the nature of the relationship between the individual and the group. How cultures resolve this affects values concerning conservatism, intellectual autonomy, and affective autonomy. The second need is to ensure responsible behavior that will maintain social order. Resolution of this issue influences member values concerning hierarchy and egalitarianism. Finally, cultures must address the relationship between humankind and the natural and social world. The institutions designed to address this need are reflected in mastery and harmony values.

Perhaps the most well-known and widely used framework for studying national culture was developed by Geert Hofstede and published in 1980. Hofstede analyzed the values of thousands of IBM employees from dozens of countries and came up with a framework based on four dimensions: individualism–collectivism, power distance, uncertainty avoidance, and masculinity–femininity. Individualism–collectivism reflects the extent to which people prefer to act on their own or as part of a group. In individualistic societies, organizations can expect higher levels of competition and self-interested actions, whereas harmony and loyalty may be the norms in collectivistic societies.

Power distance refers to what extent a society accepts the unequal distribution of power. In low power-distance cultures, managers socialize with subordinates and often involve them in decision-making processes. In high power-distance cultures, superior–subordinate relations are very formal; subordinates are expected to obey their superiors without questioning. Uncertainty avoidance reflects the extent to which people feel threatened by situations that are ambiguous or have unknown outcomes and subsequently act to avoid or control such circumstances. In cultures with high uncertainty avoidance, there is a strong preference for formal rules and guidelines; deviance from established behaviors is regarded negatively. In cultures with low uncertainty avoidance, employees are more apt to take risks and be more tolerant of behaviors and opinions that are different from theirs. Hofstede's masculinity–femininity dimension refers to certain sets of values preferred in a society. Masculine societies favor assertiveness, performance, success, money, and materialism. Feminine societies emphasize a friendly environment, job security, cooperation, quality of life, warm personal relationships, and caring for the weak. Masculine cultures are more likely to divide work and social tasks along gender lines, differentiating between jobs meant for men and those meant for women.

A third typology for distinguishing the impact of national culture on individual values is the GLOBE (Global Leadership and Organizational Behavior Effectiveness Research) project, which defines nine distinct cultural dimensions theorized to impact how leaders manage and structure their workforce. Building on Hofstede's typology, the GLOBE dimensions include uncertainty avoidance, power distance, and collectivism. However, they distinguish between two forms of collectivism: societal collectivism and in-group (e.g., family and/or organization) collectivism. Hofstede's masculinity/femininity is likewise split into a gender egalitarianism dimension and an assertiveness dimension. Finally, GLOBE adds dimensions for future orientation, performance orientation, and humane orientation, representing the degree to which individuals engage in future-oriented behaviors, reward performance improvement, and value fairness, respectively.

Cultural Values and Work-Related Behaviors

The effects of national culture on work-related behaviors are well documented. A meta-analysis by Taras et al. (2010) found Hofstede's cultural dimensions to predict a variety of organizational outcomes including job performance, absenteeism, turnover, organizational commitment, citizenship behaviors, organizational identification, and team attitudes. While cultural values accounted for relatively low amounts of variance in specific behavioral outcomes, their predictive power concerning emotions, attitudes, and perceptions rivaled – and in some cases surpassed – those of personality and general mental ability.

In their review of empirical studies using Hofstede's framework, Kirkman et al. (2006) summarized findings regarding culture's influence on individual styles of change management, conflict management, human resource management, negotiation, reward allocation, decision making, and leadership. In addition, culture was examined as an antecedent of organizational justice, work-related attitudes, and employee motivation.

Of the four dimensions, not only was individualism–collectivism the most frequently investigated, but comparatively, it tended to be the most powerful predictor of workplace outcomes. Collectivist values are associated with increased cooperation and positive attitudes regarding teams. Additionally, individuals from collectivist cultures tend to prefer nondirective leadership that emphasizes participation and teamwork. On the other hand, individualism is associated with increased conflict, and those from individualist cultures tend to use personal experience rather than formal rules to manage conflict. Individualism is positively associated with avoiding unethical behavior and preferring paternalistic leadership, and negatively associated with concern for others' interests in conflict management (Kirkman et al., 2006; Taras et al., 2010).

Individuals from high power-distance cultures tend to have higher organizational commitment, person–organization fit, and a preference for directive leadership; however, they are less likely to avoid unethical behavior and seek feedback (Kirkman et al., 2006; Taras et al., 2010). The value of uncertainty avoidance is strongly associated with an individual's team commitment and a preference for directive leadership, and negatively associated with innovation and a preference for participative leadership (Taras et al., 2010). Finally, masculinity is positively associated with a preference for a compromising conflict management style and social avoidance, and negatively correlated with a preference for an avoidance conflict management style and the value of individual equality (Taras et al., 2010).

Cultural values can also shape individual personality. In their literature review, Heine and Buchtel (2009) discussed the differences in personality across cultures, especially between Eastern and Western cultures. In Eastern societies, perceptions of the self tend to be more fluid, context-specific, and dependent on others. Easterners are more likely to have contradictory views of themselves, and they may change the way they act based on the situation. Because of the collectivist nature of many Eastern cultures, Easterners tend to act in ways that promote harmony with others. They are less likely than Westerners to engage in self-enhancing activities, perhaps because collectivist cultures may punish such actions more than individualist cultures. Western, individualist cultures, on the other hand, may provide benefits of self-enhancement that outweigh the costs, leading to its greater prevalence as a personality trait in such countries. Additionally, Westerners tend to view their personalities as stable and believe they act somewhat consistently across different situational contexts.

Despite extensive research, there remains much to do to better understand the influence of values at work. While a considerable amount of research has accumulated regarding some cultural values (e.g., individualism), others have been less explored. Moreover, paralleling the personality literature, researchers have begun to call for an exploration of more narrowly defined value facets than the broad dimensions conceptualized in the dominant typologies. In addition, process models accounting for how values develop, change over time, and impact attitudes and behaviors are needed to clarify our existing empirical findings.

Abstract

The present article provides an overview on personality assessment in basic research and applied areas of psychology. Both descriptive and explanatory models of personality and the derived methods of assessment are presented. Further personality assessment in the applied fields of psychology is introduced focusing on clinical psychology, and touching on the topic in organizational and educational psychology.

Definitions

The necessary formal aspect of a definition of personality assessment is not easy due to the nonuniformity of the personalist terminology. The terms 'person' and 'personality,' derived from the Latin words *persona* and *personalitas*, are among the most abstract expressions of our language. It is therefore not surprising to find many approaches to define the personality of a person; Allport (1937) had already compiled 50 definitions. Within everyday language, personality denotes the individual characteristics of a person, but can also have a meritorious connotation. Within recent psychology, definitions of personality are neutral and focus on stable individual differences in behavior. From an evolutionary perspective, McAdams and Pals (2006: p. 204) defined personality as "(a) an individual's unique variation on the general evolutionary design for human nature, expressed as a developing pattern of (b) dispositional traits, (c) characteristic adaptations, and (d) self-defining life narratives, complexly and differentially situated (e) in culture and social context." In the present context we focus on personality assessment as the measurement of relatively stable, traitlike interindividual differences in temperament, which become manifest in trait-relevant situations.

Backgrounds

Descriptive Approaches to Personality

Descriptive approaches to personality date back to ancient literature. A well-known example is the characterology of Theophrastus of Eresus, published around 319 BC. The rather humorous than moralizing character sketches contain typical personality traits that seem to have survived more than two millennia. Scientific personality assessment within clinical psychology started in the twentieth century. The methodological groundwork for the study of individual differences was laid by Sterns (1911) research strategies for personality psychology. After World War I, Woodworth (1919) developed the earliest self-report personality questionnaire in order to measure signs of maladjustment to military life in soldiers – the Woodworth Personal Data Sheet (PDS). It contained rationally devised items describing several symptoms of emotional distress. The PDS spurred the development of further uni- and multidimensional questionnaires for the assessment of adjustment problems in the 1920s and 1930s, with items usually constructed in a similar, i.e., rational or deductive way (for a historical overview, see Butcher, 2010). A well-known exception was the criteria-orientated development of the Minnesota Multiphasic Personality Inventory (Hathaway and McKinley, 1943), where item selection was purely based on discrimination ability between a clinical group patients and a nonclinical control group. It is still available in several versions and remains one of the most used personality measures in clinical psychology.

After World War II, exploratory factor analysis became a widely used construction method. With regard to the underlying dimensions of personality, the results of factor analytic personality research appear quite inconsistent at first glance. For instance, Cattell (1965) or Guilford (1975) proposed rather different factorial description systems of individual differences. Nevertheless, a five-factor model of basic dimensions of personality has emerged, which is represented by various authors and groups of authors (for a comprehensive account of the historical development of the five-factor model, cf Digman, 1994). Lexical analysis of personality description terms and joint factor analyses of existing personality measures repeatedly revealed five broad factors, 'neuroticism,' 'extraversion,' 'openness to experiences,' 'agreeableness,' and 'conscientiousness.' Costa and McCrae (1995), major proponents of the model, argue that this relatively small number of dimensions captures the major variance in the personality descriptive terms: "What the model hypothesizes is that almost every personality trait is substantially related to one or more of the five factors, and that any remaining traits … form a miscellaneous category rather than covarying to define a sixth or subsequent factor" (p. 218).

The five-factor model is currently considered the standard in the field of personality theories for global and comprehensive assessment of personality. Several measures exist, the most prominent being the NEO-Personality Inventory (NEO-PI), which is available in a revised as well as a shortened version (Costa and McCrae, 2008). Although primarily a measure of normal personality variation, the NEO questionnaires can also be used in clinical settings (Costa and McCrae, 2008). Similar to other personality inventories, response patterns of clinical and nonclinical subjects in the Revised NEO Personality Inventory (NEO-PI-R) were structurally invariant (O'Connor, 2002b).

In addition to the five-factor model for a global and comprehensive assessment of personality, a variety of constructs and associated measures exist for assessing specific personality traits. Within personality research it is still controversial to what extent variance observed in specific constructs is not already covered by the five factors or if, on the other hand, relevant dimensions are missing in the five-factor model (e.g., O'Connor, 2002a).

Explanatory Personality Models

Several psychobiological personality models emerged in the second half of the twentieth century, aiming to explain mechanisms underlying individual differences in personality. The theories of Eysenck (1967) and Gray (1982) combined basic personality dimensions with differences in arousal, in the sensitivity to cues of reinforcement, and the sensitivity to cues of punishment. In these theories, individual differences in cognition and motivation are based on underlying biological characteristics and refer to basic psychological constructs.

Eysenck's temperament theory (e.g., Eysenck, 1967) includes basic orthogonal dimensions of personality and underlying hypothetical neurobiological models. Basis of the measurement and classification of personality traits were factor analyses with which the theoretically assumed personality structures should be uncovered. In its early conception Eysenck's personality model comprised two basic dimensions, which he described as 'introversion–extraversion' and 'neuroticism.' Later Eysenck and colleagues added a third dimension, 'psychoticism,' linked to behaviors such as lack of empathy, aggression, and impulsivity (see Eysenck et al., 1985). The success of this dimensional classification system lay in the fact that the two dimensions of extraversion and neuroticism are found in virtually all factor analyses of trait judgments that are based on a sufficient number of traits. The differentiating aspect of Eysenck's approach (compared to the aforementioned factorial description systems) is the anchoring of the personality dimensions in neurobiological systems. Eysenck (1967) suspected the biological bases of individual differences in neuroticism and extraversion in interindividual differences in neurophysiological excitation and inhibition processes. To assess the three dimensions, Eysenck and colleagues devised the Eysenck Personality Questionnaire (EPQ) in a revised version (see Eysenck et al., 1985; EPQ-R).

Gray (1982) proposed a modification of Eysenck's theory, based on animal learning theory. In his two-dimensional temperament system, two behavioral systems play a crucial role that come into play in emotional situations. A Behavioral Activation System (BAS) organizes the response to conditioned stimuli that signal positive reinforcement (reward) or negative reinforcement (nonpunishment), and leads to approach or active avoidance behavior. A Behavioral Inhibition System (BIS) organizes the response to stimuli that are unknown or signal nonreward or punishment. This leads to behavioral inhibition and to an increase in limbic arousal and attention. Individual differences of these two systems yield two orthogonal dimensions that were described by Gray as 'anxiety' and 'impulsivity.' In Gray's theory extraversion and neuroticism represent derivations of these more fundamental factors. Anxiety ranges from 'low extrovert and highly neurotic' (equivalent to high anxiety) to 'highly extroverted and low neurotic' (equivalent to low anxiety). High impulsivity corresponds to 'strongly extroverted and highly neurotic,' low impulsivity to 'low extraverted and low neurotic.' With increasing anxiety, susceptibility to nonreward, punishment, and unknown stimuli increases. Increased impulsivity is associated with susceptibility to reward and nonpunishment. In a modification of Eysenck's theory extraverts are no harder to condition than introverts, but rather more sensitive to punishment or the threat thereof, as well as more sensitive to reward and positive affirmation. In 2000, Gray and McNaughton presented the revised Reinforcement Sensitivity Theory (r-RST). Similar to Gray's original theory, they assumed three biological systems with similar names (a BAS, a BIS, and a Fight-Flight-Freeze-System (FFFS)), which are anatomically separated but functionally related.

To assess the two dimensions sensu Gray's original theory, the most widely used measure to date are the BIS/BAS scales developed by Carver and White (1994). Jackson (2009) developed scales to separately tap the BAS, BIS, FFFS of the r-RST. Recently, Corr and McNaughton (2012) provided another refinement of this line of thinking reviewing evidence on approach and avoidance personality. Further psychobiological models of personality partially influenced by Gray were developed by Cloninger (1994) and Zuckerman (1991).

Clinical Psychology

The assessment of individual differences in personality has a long tradition in the fields of clinical psychology and psychiatry. Today it is widely accepted that personality plays a crucial role in several clinical issues, including, for example, etiology of mental disease, pathoplasticity, treatment efficiency, or risk for disorder relapse. For instance, several dispositional traits (e.g., neuroticism) have been shown to contribute to an individual's capability to cope with both daily stressors as well as severe negative life events. Personality is therefore closely linked to the concepts of vulnerability and psychological resilience, adding to a person's risk to develop mental illness. Thus, the consideration of personality traits is not only helpful but often crucial to understand the pathogenesis of certain psychopathological disorders. Based on personality measures, at-risk individuals may be identified and introduced to early prevention treatment. Generally, a comprehensive knowledge about a patient's personality can help clinicians in choosing appropriate therapeutic interventions, since some psychotherapeutic techniques and/or pharmacological treatments may work out well in some persons but not in others. Accordingly, personality traits often have a high prognostic value with regard to therapeutic effects or even disorder relapse. Finally, personality measures are frequently used as outcome measures, providing important information about the achievement of therapeutic goals. As personality is not absolutely stable but may substantially change during and/or after a pathological episode, one should generally distinguish between premorbid, morbid, and postmorbid personality.

In most of the available studies on the relation between personality and psychopathology self-report questionnaires

have been used for personality assessment. This practice is probably fostered by the low temporal and economic expenses of such questionnaire measures. However, this approach also entails several potential problems as the ability to correctly assess the own personality can be strongly affected by the current state (e.g., negative mood, limited self-insight) and, therefore, by the disorder itself. Moreover, self-report measures of personality and psychopathology often share a considerable number of similar items, resulting in high common method variance. This may lead to an overestimation of the personality–psychopathology relationship. For some individuals (e.g., preschool children) questionnaires are even totally unsuitable. To overcome some of the problems of self-report inventories, future research may therefore more frequently use other types of personality measures, such as interviews, informants' reports, or observational measures.

As mentioned above the relation between personality and psychopathology is manifold and any attempt to provide a complete overview here could only fail. Below, we therefore exemplarily describe some aspects of the personality–psychopathology interrelation, also considering the issue of personality assessment.

Affective-Motivational Personality Constructs and Psychopathology

Over the last century several dimensional models have been proposed, in which personality has been mainly described in terms of affective-motivational dispositions. Most traits described in these models can be subsumed under or are related to the broad concepts of negative emotionality/neuroticism (NE/N) and positive emotionality/extraversion (PE/E) (e.g., Markon et al., 2005). In adults and adolescents, traits in the spectrum of NE/N and PE/E are typically assessed using self-report questionnaires like the EPQ (Eysenck et al., 1985), the NEO-PI-R (see Costa and McCrae, 2008), or the Temperament and Character Inventory (Cloninger, 1994). Child temperamental traits related to NE/N (e.g., behavioral inhibition) have been assessed in many ways using, for example, retrospective self-reports or behavioral observations (e.g., Caspi et al., 2003). For obvious reasons, a vast number of studies have investigated whether and how NE/N is related to mood disorders. With regard to unipolar depression the role of NE/N seems to be manifold, with NE/N and depression sharing common etiological influences, NE/N predicting the onset and course of depressive episodes, and NE/N interacting with negative life events in increasing the risk for depression (for an overview see Klein et al., 2011). NE/N is also increased in individuals with a bipolar disorder. However, unipolar versus bipolar mood disorders also strongly differ with regard to their relation to low-order personality facets (e.g., Quilty et al., 2013). Using multifacet inventories like the NEO-PI-R may therefore provide important differential diagnostic information. Besides its' role in the context of mood disorders, NE/N is linked to other forms of mental disease (especially, anxiety disorders) as well as general health problems, pointing to a rather unspecific relation between NE/N and (psycho-) pathology. This, however, also indicates that NE/N contributes to comorbidity among many mental disorders (for a general overview of the role of NE/N in psychopathology, see Lahey, 2009). With regard to PE/E and its role in psychopathology the existing literature is less consistent. For instance, while some studies report low PE/E in patients with unipolar depression others did not report such an association. Facets of PE/E that are closely related to appetitive motivation (e.g., novelty seeking and sensation seeking) have been repeatedly found to be associated with a higher risk for substance abuse, or problematic gambling (e.g., Zuckerman and Kuhlman, 2000).

Personality Disorders

When it comes to the topic of personality and psychopathology the probably most obvious link, by definition, lies in the field of personality disorders. There is vast number of available tools for the assessment of maladaptive personality functioning, including symptom checklists (e.g., the Psychopathy Checklist Revised Hare, 2003), self-report inventories (e.g., the Millon et al., 2009), or diagnostic interviews (e.g., the Structured Clinical Interview for DSM-IV Axis II Disorders First et al., 1997). In the classification systems for mental diseases (International Classification of Diseases (ICD) and Diagnostic and Statistical Manual of Mental Disorders (DSM)), personality disorders have traditionally been conceptualized as distinct categories, i.e., a personality disorder is diagnosed when a predefined threshold is exceeded. This practice has received much criticism, and calls have been made for a more dimensional conceptualization and multitool-based assessment of personality disorders (e.g., Clark, 2007). However, the categorical model of personality disorders was kept in the official classification system (Section II) of the most recent 5th edition of the DSM, while a hybrid categorical-dimensional model has been introduced only in DSM-V Section III under the label of 'Emerging measures and models.' Although this categorical-dimensional model was also criticized because of its low practicality in daily clinical work and lack of empirical support (e.g., Verheul, 2012) it might be, at least, a starting point for a more dimensional conceptualization of personality disorders in future editions of DSM and/or ICD.

Dispositions of Self-Regulation

The term self-regulation is a very broad one, referring to an individual's capabilities and strategies to regulate one's emotions, behaviors, and cognitions in order to achieve certain goals (e.g., completing a certain task, avoiding distress, or maximizing pleasure). It comprises several other concepts such as emotion regulation, effortful-control, coping, or self-efficacy. In the field of clinical psychology, habitual tendencies in self-regulation have been investigated, for example, with regard to their role in stress vulnerability/reactivity and therapeutic outcomes. For instance, the personality trait of conscientiousness (i.e., the individual's tendency to set and keep long-range goals and inhibiting impulses that may interfere with these goals) is negatively associated with depression, thereby also interacting with NE/N. High conscientiousness combined with low NE/N is also linked to increased treatment efficiency (Klein et al., 2011). NE/N, PE/E, and conscientiousness are also related to coping styles, with PE/E and conscientiousness being positively correlated with engagement coping (i.e., dealing with the stressor or the resulting negative emotions) and NE/N being positively correlated rather with disengagement coping

(i.e., avoiding to deal with stressor or resulting negative emotions; Connor-Smith and Flachsbart, 2007). Conscientiousness (like NE/N and PE/E) is typically assessed with self-report questionnaires like the NEO-PI-R. In children, effortful-control (i.e., the ability to inhibit a dominant response) is a frequently investigated temperament that is closely related to the concept of executive control/attention. It has been shown that low effortful-control in childhood predicts divers forms of psychopathology and maladjustments later on (Nigg, 2006). Individual differences in children in effortful-control have often been assessed using behavioral observations in attentional tasks (e.g., Rothbart et al., 2003). Finally, perceived self-efficacy is related to diverse aspects of health behavior (O'Leary, 1985). Thus, stable tendencies in the attribution and perceived control of behavioral outcomes influences the individual's stress reactivity and health status (e.g., Roddenberry and Renk, 2010). Several self-report scales are available to assess such tendencies in perceived self-efficacy and locus of control (see, e.g., Furnham and Steele, 1993).

Organizational Psychology

Assessing personality in organizational settings is an important application of personality psychology, and has been a driving force in the development of personality theory and assessment. In organizational practice, personality assessments are mostly utilized for personnel selection; additionally, other important areas include the assessment of personality for personnel development, placement, and career counseling. Hundreds of thousands of assessments are conducted each year around the world, which provide valuable information for both test takers and organizations, for example, by providing valuable information to take well-informed career decisions or to staff individuals who will perform well and contribute to the success of the team and the organization. Despite these applied purposes, investigating personality in organizational settings also advances our knowledge regarding the personality constructs themselves, as convergent and discriminant validities with theoretically associated criteria give important information regarding the construct domain of a personality trait.

Broad Dimensions of Personality

The significance of personality traits for predicting job performance has been investigated so often that, in the meanwhile, second-order *meta*-analyses have been conducted (Barrick et al., 2001). Regarding the Big Five, the factor most strongly associated with job performance is conscientiousness. Corrected for unreliability in the predictor and the criterion, range restriction, and lack of construct validity an average coefficient of 0.27 has been obtained. Across studies, the validity of conscientiousness has been shown to generalize across different criteria (supervisory ratings, objective performance indicators, teamwork) and across occupations (sales performance, managerial performance, professionals, police, skilled, or semiskilled). A reason for the consistent, even though only moderate correlation might be that individuals with high, compared to low levels on conscientiousness are more likely to be on time, to keep their workplace tidy, to perform their tasks in a structured manner, to deliver orders within the prescribed time limit, to maintain a high standard of quality, to engage in the task, and to reassure the quality of their work. Interestingly, the relatively high correlation of conscientiousness with job performance is mirrored by correlations with other criteria of intellectual performance, such as school and academic performance (Poropat, 2009).

Additionally to conscientiousness, generalized validity for job performance has also been found for emotional stability, even though the coefficient of 0.13 is rather small. Contrary, openness to experience, agreeableness, and extraversion are only marginally correlated with general job performance. At most, correlations can be found for specific criteria or occupations. For example, extraversion and openness for experience have been found to predict training performance, and extraversion has been found to predict performance in managerial positions and, to a smaller degree, for police officers.

In light of the relatively small correlation coefficients, the relevance of personality traits for predicting job performance has been criticized (see Tett and Christiansen, 2007, for a discussion). For its application in high stakes situations like personnel selection, an additional problem is social desirability, i.e., the tendency to euphemize self-reports of personality to maximize the probability for a job offer.

Narrow Facets of Personality

While the investigation according to the Big Five model of personality has largely helped to compare results across studies, there are hints that the Big Five might be too broad for predicting job performance (Tett and Christiansen, 2007). For example, Mussel et al. (2011) found the facet openness to ideas to significantly predict job performance, but found negligible correlations for the remaining facets as well as the Big Five factor openness to experience. Judge et al. (2013) compared the predictive validity of facets, compared to Big Five traits *meta*-analytically. They found higher validities for facets, compared to the Big Five, which explained approximately twice the variance. Differential validity for facets was especially pronounced for openness to experience, emotional stability, and extraversion.

Additional evidence for the significance of personality for job performance provides so-called Criterion Orientated Personality Scales (COPS, Ones and Viswesvaran, 2001). COPS are personality traits, which were specifically developed for predicting job performance. For example, significant prediction of job performance around 0.40 has been found for integrity tests, which were initially developed for predicting deviant behavior such as stealing, or mobbing. Similarly, personality scales assessing customer service orientation have been found to significantly predict job performance.

A final view regarding the role of personality in organizational settings takes a look from the dark side. Therefore, the question is not whether certain personality traits predispose the likelihood of succeeding at work, but rather at predictors of failure. Compared to the studies discussed so far, this approach has not so much been guided by the Big Five personality traits. Recently, the so-called dark triad of personality, consisting of narcissism, machiavellianism, and psychopathy, has received increasing attention (e.g., Furnham

et al., 2013). In the work context, high levels on the dark triad has been found to be associated with counterproductive work behavior, the tendency to manipulate individuals in pursuit of selfish gains ('snakes in suits'), and criminal activities, such as shoplifting. However, individuals with high levels on the dark triad also have a strong desire for power and a strong motivation to be very rich, which should be advantageously related to career success, especially when combined with other factors, like intelligence or physical attractiveness (Furnham et al., 2013). Disentangling these opposing effects for diverse organizational outcome variables will be an important endeavor for the future.

Educational Psychology

Personality assessment in educational contexts comprises all temperamental and personality traits, habits, and states that are relevant to academic learning (Braden, 2003). Temperament and personality measures can be applied to single persons during psychological school service or in connection with educational research or achievement tests in school studies, cross-national, or large-scale school studies. The main focus of personality assessment lies on the child or young adult as the individual learner. Personality characteristics are relevant to educational contexts because they can serve as vulnerabilities and protective factors in achievement situations and influence the development of learning disorders (e.g., Hasselhorn, 2008). Learning-related questions and problems comprise a wide range of aspects from learning disabilities and learning disorders to high achievers and giftedness. In the last decade the focus of personality assessment in educational contexts was extended to personality characteristics of peers and teachers that can influence successful learning in various ways. Personality assessment in educational contexts deals with the problem that personality traits develop during childhood and adolescence (e.g., attribution stile, volitional control abilities) and that a broader and more differentiated construct of personality does not come up until late childhood. The choice of personality assessment in educational contexts thus depends on the cognitive development of the learner and can vary between younger and older children.

In educational contexts broad personality inventories are used less often because various broad personality traits are not strongly related to learning outcomes. However, consciousness and emotional stability seem to be important for learning to some degree and they appear to go along with higher academic performance (e.g., Poropat, 2009). It is interesting to note that the latter two traits are also highly relevant for both clinical and organizational assessment (see above). Yet, in light of the weak relations for broad personality traits (Big Five, etc.), research focused on more narrow, single personality characteristics that are central for learning. These specific personality characteristics are assessed frequently in educational contexts and are relevant to most of the school service problems and questions. The selection of possible personality characteristics always depends on the concern of the school service and on the age or cognitive ability level of the child (e.g., learning disorder, learning disability, achievement drop, giftedness, aggression, anxiety). The most important specific learning-related personality characteristics are motivation and volition (see section below and cf Hasselhorn, 2008).

Domains and Methods of Assessment

Temperament characteristics, in particular more narrow aspects, are of particular interest for educational contexts because they can be applied early in life, and they are relevant for various learning-related behavioral outcomes (e.g., inhibition). The most commonly used temperament dimensions are activity level, anger/frustration, behavioral inhibition/fear, effort control, and positive affect (Zentner and Bates, 2008). These temperament dimensions do not represent a single theory rather they are a consensus of researchers about the most important dimensions (Zentner and Bates, 2008). Temperament dimensions can be measured by self-report interviews and questionnaires, other-report questionnaires, behavioral observation, and psychobiological measures. Depending on the concern, a multimethod approach should be preferred, to validate the single measures and to cope with the weakness of each method. In educational contexts temperament characteristics are measured mainly by self-report (child interview, questionnaire) and other-report instruments (parent questionnaire, teacher questionnaire) that often contain behavioral observations (child in school and/or family context; for an overview see Zentner and Bates, 2008).

Motivation and Volition

Motivation and the achievement motive system play a central role for learning. It is the first relevant precondition for successful learning (Hasselhorn, 2008), it should be part of personality assessment in an educational context, and its measurement has been debated intensively in the past (e.g., Hulleman et al., 2010). The quality of the individual achievement motive system comprises the three aspects (1) success orientation or fear of failure, (2) attribution style, and (3) self-concept of competences (Hasselhorn, 2008). The development of achievement motive is observable in the attributions children employ to explain their success or failure and becomes relatively stable in early adolescence (Hasselhorn, 2008). Overoptimism, unrealistic wishful thinking, and a lack of social comparisons are defense mechanisms of the achievement motive system that play a major role in the development of competency beliefs and are characteristic for young children (Hasselhorn, 2008). The excessively optimistic self-concept of children in their first two school years descents and a more realistic school-related self-concept is developed. In this process, using the individual reference norm instead of social reference or criteria norms supports a positive development of learning and the achievement motive system. In contrast, if protective mechanisms of self-esteem are not available, external attributions to the own success may develop and can become a risk factor of a failing individual achievement motive. Children with ongoing experiences of failure are at high risk to develop a weak belief in their own competences and may lose the ability to use cognitive resources and metacognitive abilities available to them. All of the risk mechanisms in turn increase the probability to develop psychological symptoms like anxiety,

depression, aggression, psychosomatic symptoms, or learning disorders (Vahia et al., 2011).

Volition is the second critical precondition for successful learning (Hasselhorn, 2008). In addition to motivation, volitional control of behavior is necessary to realize learning intentions and learning goals. For example, Shoda et al. (1990) showed that reward gratification increases with increasing age and the presence of this capacity at preschool age goes along with more self-confidence, higher frustration tolerance, and achievements in school. Besides these findings, delay gratification remains difficult for some adolescents and adults indicating that a temperamental component might be critical for initiating control. Nevertheless in demanding contexts volitional control of behavior necessitates strategies of metacognitive regulation that develop relatively late (cf Hasselhorn, 2008).

Abstract

The present article summarizes key findings from faking research. The article starts off by comparing different definitions for the phenomenon. Afterward faking behavior is placed in a nomological net of social desirable responding. The article continues by presenting empirical findings for the main research questions, i.e., the existence of faking, its impact on a test score's validity, and ways of measuring or preventing faking. Throughout the presentation of these issues, a broad perspective is taken including a variety of even contrasting findings. The article concludes with a summary and an outlook.

What do academic success, job performance, getting a divorce, and life expectancy have in common? The answer to this general question is that each one of these outcomes is predicted by interindividual differences in personality traits, especially the Big 5 and its facets (Roberts et al., 2007). These and other meta-analytical findings are the reason why personality differences are considered important in all kinds of selection settings. Moreover, there are also longitudinal studies showing that personality traits are predictive above and beyond general mental ability for academic success (Ziegler et al., 2009, 2010a), vocational training (Ziegler et al., 2014), job success (Lindqvist and Vestman, 2011), and lifelong learning (Ziegler et al., 2012).

Despite the overwhelming empirical evidence supporting the usefulness of personality traits for predicting important life outcomes, there is a long-lasting debate based on criticism regarding the assessment method of choice: self-reports. Cattell (1958) differentiated three media for personality assessment: life record observations or life data (L-data), questionnaire data (Q-data), and (objective) test data (T-data). In spite of the early description of these three ways, especially Q-data are used today to assess interindividual personality trait difference by administering self-report questionnaires. Regardless of the above-mentioned success of such questionnaires in terms of test criterion correlations, two major criticisms have been raised again and again.

McClelland (1987: 11) stated "A scientist cannot believe what the people say about their motives." This quote most of all was due to the idea that motives should be differentiated in self-attributed motives (can be measured with self-reports) and implicit motives (cannot be measured with self-reports because they are not accessible with introspection). While McClelland meant to scourge the use of questionnaires to assess motivation, his famous quote has been used to depreciate self-reports in general. Much could be said about the more or less fruitful attempts to capture personality traits with so-called implicit measures. In addition to the theoretical differentiation between implicit and explicit traits (Hofmann et al., 2005; McClelland et al., 1989), the varied operationalizations for implicit traits ranging from picture story tests to implicit association tests have all met considerable measurement problems (Ziegler et al., 2010b). Thus, this criticism against self-reports continues to be weakened by the lack of empirical evidence strongly supporting alternative measurement approaches.

The second criticism brought forward against self-reports is that the answers people give can easily be distorted. Especially, response behavior that systematically distorts self-reports from reality toward a more favorable impression, so-called *social desirable responding* (SDR), is regarded as problematic. Paulhus (2002) wrote a seminal chapter in which he summarized the history of research on SDR. His summary finishes with an integrative model of SDR. Within this model, Paulhus describes two general themes (an egoistic and a moralistic bias) that are crossed with two different addressees (self and other) resulting in four kinds of SDR: self-deceptive enhancement, agency management, self-deceptive denial, and communion management. The use of personality self-reports for selection purposes is especially endangered if the test-taker aims his or her distortion at someone else (the potential employer) to appear in a certain way. This kind of behavior is often called faking. Thus, faking should not be confused with SDR. Rather than that faking can be seen as a subform within the SDR framework by Paulhus (2002). Nevertheless, faking is potentially a serious threat for the utility of self-reports, especially in high-stakes situations (i.e., situations in which the test-taker can gain something based on the self-report results).

Definition of Faking

In terms of a nomological net faking might therefore best be positioned within the SDR framework provided by Paulhus (2002) as agentic or communion management. However, this broad categorization has to be complimented with a sound definition of the actual phenomenon in order to avoid confusion. MacCann et al. (2011: 309) summarized definitions from experts in the field of faking research and concluded that all experts agreed upon four key elements: "(〈〈〈) faking is a behavior rather than a trait, (嶋) faking requires motivation (i.e., it is goal-oriented), (嶇) faking behavior results in an inaccurate or enhanced impression, and (帙) faking involves the interaction of person (traits) and situational factors (environmental influences)." Most experts also saw faking as an intentional and conscious act. Based on these key characteristics of faking, the following chapter adopts a definition provided by Ziegler et al. (2011: 8) who define

faking as "a response set aimed at providing a portrayal of the self that helps a person to achieve personal goals. Faking occurs when this response set is activated by situational demands and person characteristics to produce systematic differences in test scores that are not due to the attribute of interest."

Faking as a Response Set

Jackson and Messick (1958) distinguished between response styles (those phenomena that occur across time and different questionnaires) and response sets. Paulhus (2002) also uses these terms and sees response sets as short-lived response biases. More importantly, such response sets are caused by temporary distractions or motivation. In other words, faking behavior does not occur always. Instead, test-takers fake due to some situational characteristics.

Faking as a Means to Achieve Personal Goals

One important aspect of the definition provided above is that faking does not occur without a specific goal. This means test-takers have a specific personality profile in mind when faking, believing that portraying this profile will help them to gain something out of the situation they are in. Such a profile could be the profile of the ideal employee for the offered position (Bowen et al., 2002) or a very specific personality profile for a specific job (Pauls and Crost, 2005). In both cases, matching the profile will increase the chances of getting the job in a selection scenario.

This goal directedness bears important implications for faking research. Whenever effects of faking are to be researched, samples need to be used that have a highly similar goal in mind. In that sense, combining applicants for different jobs into one sample potentially blurs faking effects (Birkeland et al., 2006). Using think aloud protocols, Ziegler (2011) could show that test-takers match their answer in a self-report to their knowledge and implicit theories about the job they are applying for. Thus, if a sample contains test-takers who have different job profiles in mind, the faking results will be different and potentially even reversed.

Faking as an Interaction between Person and Situation

As mentioned above, faking behavior occurs when situational demands call for it. However, not everyone fakes and those who fake do not all end up with the same test score. Thus, individual differences in faking behavior exist. Ellingson (2011) states capability to fake, believing in the necessity to fake, and the belief that the opportunity to fake is valued as important interindividual differences determining if and how much a person fakes.

Finally, this definition implies that faking occurs most often in so-called high-stakes situations. Especially, selection procedures such as job selections constitute the natural setting for researching faking and its effects. Therefore, within the rest of this article, faking behavior will always mean that test-takers distort their responses to a self-report measure of personality in order to achieve a personal goal in a specific (high stakes) situation. Whereas this specification helps to mark the playground for faking research, there is the question whether faking behavior actually exists.

Does Faking Really Exist?

There is a lot of evidence that faking behavior can be elicited in the lab (e.g., Ziegler et al., 2007). However, lab studies have been criticized for their lacking ecological validity. Moreover, results from empirical studies using real applicant data seem to suggest that faking does not exist outside of the laboratory. Hogan et al. (2007) published results from an impressive data set of applicants. The findings show only little differences (Cohen's $d < |.15|$) in the Big 5 domains between applicants and a research sample. While the size of the data set itself is impressive, the results are difficult to interpret without knowing the specific jobs the applicants applied for. As mentioned above, in order to prevent different job expectations from blurring faking effects, job homogeneous samples are necessary. Whether the applicants in the paper presented by Hogan et al. all applied for the same job remains unclear, though. The idea that job homogenous samples are needed is supported by meta-analytical findings from Birkeland et al. (2006). Those authors showed that job characteristics (sales vs nonsales and management vs nonmanagement) moderate extend and direction of faking behavior.

Griffith et al. (2007) introduced a method based on the ideas of true scores and test score reliability from classical test theory. Within this framework it is assumed that each person possesses a so-called true score, i.e., the true standing of that person on a latent variable. However, assessing this true score is virtually impossible because nonsystematic errors distort single measurements. Multiple measurements of the same trait for one person would yield a normal distribution with the true score as a mean and the error determining the variance. Therefore, when administering a questionnaire, a random sample out of this intraindividual distribution is drawn. In order to estimate the true score, a confidence interval around the measured score can now be estimated based on the test score's reliability and a set error probability (usually 5%). Griffith et al. have applied this general approach to individual assessments in order to estimate the amount of people faking in an applicant setting. They used a data set of applicants who had filled out a personality questionnaire twice, once in an applicant setting and the second time in an anonymous research condition. Griffith et al. estimated a confidence interval around the score from the anonymous condition. Depending on the kind of interval used, 30 to 50% of the applicants had scores under applicant conditions that were outside of their confidence interval. Thus, faking behavior occurs in reality and can be verified using methods based on ideas from classical test theory.

Does Faking Matter?

Whether faking matters or not is harder to answer. First of all, it has to be noted that most research conducted in order to answer this question used some kind of real or simulated job applicant condition. There is research within the clinical area,

looking at faking (i.e., malingering) within a clinical context (Hall and Hall, 2011) which is not discussed here.

Usually, when the impact of faking behavior is discussed, three different outcomes are looked at construct validity, test criterion correlation, and selection outcome. Whereas the first two outcomes generally use group statistics such as correlations, the latter one looks at the actual selection results and therefore, might be the most important in terms of practical implications.

Faking and Construct Validity of a Test Score

Important aspects of a test score's construct validity are the correlations with other test scores close by in the nomological net. Moreover, the factorial structure of the questionnaire used oftentimes is a key issue. Using structural equation modeling early work in this area suggested that faking behavior did not affect construct validity (Ellingson et al., 2001; Smith and Ellingson, 2002). However, two issues raise questions with regard to this interpretation. First of all, in order to identify a subsample of fakers, high scores in so-called social desirability scales were used. As will be outlined below, by now it seems clear that such scales are no reliable indicators of faking behavior. Secondly, in order to fit the models, the authors had to include a number of correlated residuals. Based on the definition given above, such correlated errors might be exactly the manifestation of faking behavior (Schmidt et al., 2003).

Other research suggests that correlations between test scores increase when the test-takers fake with a similar faking goal (Pauls and Crost, 2005). Moreover, Ziegler and Bühner (2009) also used structural equation modeling in combination with an experimental design and could show that test scores that were faked have stronger intercorrelations. More importantly though, a multiple group structural equation model was used to show that faking can be modeled as a common method variable. This approach decreased the intercorrelations between faked scores almost to zero. The large mean differences between a faking and an honest condition also disappeared. Thus, the approach allowed to remedy the effects of faking behavior on the mean score as well as construct validity of a test score and causally attribute them to a faking instruction. It has to be noted though that these findings can be criticized due to the fact that all this research was conducted in a lab.

Thus, there is strong empirical evidence that suggests effects of faking behavior on a test score's construct validity. However, this needs to be tested outside of the laboratory.

Faking and Test Criterion Correlations

As before, there is mixed evidence regarding the effect of faking on test criterion correlations. An early meta-analysis suggested that faking does not harm or influence test criterion correlations (Ones and Viswesvaran, 1998). However, faking in this meta-analysis was operationalized using social desirability scales which are problematic indicators at best (see below). The study by Ziegler and Bühner (2009) also showed no negative effects of faking behavior on test criterion correlations. But, as was criticized before, these findings were derived from lab data. Again using lab data, Ziegler et al. (2010a) could show that faking does distort test criterion correlations. The new perspective in this study was an aim on personality facets and not domains as was the case before.

Thus, as was the case with construct validity, further research using real applicant data from job homogeneous samples is needed.

Faking and Selection Outcomes

No one seems to argue against the fact that if faking occurs, it should change a test score's group mean into the desirable direction. Considering the evidence provided above that faking actually occurs in real job applicant settings, such mean changes seem inevitable. However, if all test-takers faked to the same amount, this mean-level change would not affect a selection procedure. Considering the definition of faking presented above as well as the moderating variables suggested by Ellingson (2011) and others, it seems likely that people differ in their amount of faking. This in turn would greatly affect selection outcomes. In fact, a study by Converse et al. (2009) revealed the effects of faking on top-down selection processes using a Conscientiousness scale only or multiple predictors. Depending on the selection ratio and other criteria, the percentage of applicants getting selected because they faked in the Conscientiousness measure ranged between 5% and 14% in a multiple predictor selection process. Using only the Conscientiousness scale could yield up to almost 30% of applicants getting selected because they had faked.

Thus, this research shows practical consequences. Whenever faking seems likely to occur in a selection process, multiple predictors (e.g., ability tests or interviews in addition to self-reports) should be used. It seems reasonable to apply a self-report as a first step to select out before other selection tools are applied.

Can We Measure and Correct for Faking?

If it were possible to measure faking, it would also be possible to correct potential detrimental effects. Therefore, numerous different ways have been tried to measure faking behavior. The most important seem to be social desirability scales, over-claiming, and item response theory (IRT)-based approaches.

Social Desirability Scales

Using embedded items within a questionnaire or whole scales within a test battery in order to assess faking is anything but new. The general idea is that such items ask for behavior that is common but highly undesirable (e.g., littering) or behavior that is highly desirable but rather uncommon (e.g., always telling the truth). The most important problem with this operationalization is that it is possible that test-takers actually possess the trait level that is considered highly unlikely. They would mistakenly be flagged as fakers. Moreover, test-takers often do not feel that 'never' really means 'never.' In that sense, some might think of themselves as someone who only lies in order not to hurt someone. This, however, can be seen

as positive. Therefore, the test-taker might think that such behavior is not meant, giving the statement never to lie a high agreement rating. Again, this person would erroneously be flagged as a faker. Tellegen et al. (2006) wrote "The most important and sophisticated program of inventory development to have been predicated on the idea of a general and separately measurable social desirability dimension ended up abandoning that construct" (p. 150). Paulhus (2011) also came to a generally negative conclusion: "Unfortunately, some researchers continue to indict the validity of self-report instruments if they show high correlations with SDR measures" (p. 152). Thus, all in all, it has to be said that social desirability scales are not useful to assess faking (see Griffith and Peterson, 2008 for a more detailed review).

Overclaiming

Overclaiming is a technique that was first used in marketing and brought to psychologists' attention through the work of Paulhus (Paulhus, 2011; Paulhus et al., 2003). The general idea of this technique is to have test-takers rate their familiarity with specific terms (e.g., historical events, artists, vocabulary). Some of these terms, the so-called foils, do not exist, though. Thus, test-taker claiming to be familiar with these terms exaggerate the extend of their knowledge. Using formulas from signal detection theory it is then possible to estimate a bias score as well as an accuracy score. The former is used as an indicator of response distortion. However, research so far has placed overclaiming into the category of self-enhancement. Applying the definition from above, such a behavior might not qualify as faking behavior if it occurred unintentionally.

Bing et al. (2011) used an overclaiming measure to capture faking in an applicant setting. Moreover, those authors could show that overclaiming behavior actually suppressed unwanted error variance in personality test scores. Ziegler et al. (2013) could show that a short measure of overclaiming consisting only of 15 items might be used to identify SDR in an interview.

Thus, overclaiming, despite appearing to be conceptually too far away from faking behavior, has shown promise as a means of actually capturing faking variance. In how far this might be useful on an individual level, i.e., in selection contexts, remains an open question, though.

IRT-Based Approaches

Zickar and colleagues applied so-called mixed Rasch models (MRMs) to identify fakers (Zickar et al., 2004; Zickar and Robie, 1999). MRMs are a mixture of Rasch models and latent class analysis. This allows to identify qualitatively distinct response patterns, representing faking sets while maintaining the assumption of a continuous trait measured at the same time (Rost et al., 1997). Results derived from applying this method to applicant data repeatedly have suggested two distinct faking response sets: slight and extreme faking. Recently, this interpretation has been challenged due to the overlap of these response sets with middle and extreme point responding, response sets found in anonymous situations (Ziegler and Kemper, 2013). Moreover, Zickar and Sliter (2012) summarized that IRT models so far have shown only limited success in identifying individual fakers.

Other Techniques

There are a number of other approaches to measuring faking, e.g., word use (Ventura, 2011), decision trees (Lukoff, 2011), the Bayesian truth serum (MacCann et al., 2011), or anchoring vignettes (Buckley, 2009), to name just a few. All of these approaches have some merits but also substantial problems.

Therefore, a summary at this point must come to the conclusion that there is still much to learn about faking behavior before a successful measurement method can be designed. Consequently, corrections for faking are equally elusive.

Can We Prevent Faking?

There are two general approaches trying to prevent faking. The first approach tries to create a fake-proof questionnaire. The second approach tries to reason with the test-taker.

Fake Resistant Measures

Bäckström et al. (2009) have suggested the use of neutralized items. Such items are phrased in a way that makes them neither socially desirable nor undesirable. Their empirical evidence shows that a general evaluative factor underlying all personality test scores can dramatically be reduced using neutralized items. However, if we apply the definition for faking provided above, the neutralized items seem to tackle the issue of self-enhancement or denial. Research showing that such items could be used to reduce faking is missing. Moreover, the authors themselves did not construct the items in order to reduce faking but refer to social desirability in general.

A technique clearly designed to reduce faking is the pairwise preference model (Stark et al., 2011). Questionnaires using this approach present the test-takers with item quadruples. Each of those usually contains four items and test-takers have to choose which item they agree with the most and which item the least. The items are matched on their desirability making it impossible to achieve an overall positive impression simply by using high ratings for all items as is the case in a typical Likert scale questionnaire. Such forced choice items have been criticized because of their inability to capture interindividual differences. However, recent statistical developments allow to overcome these problems (Brown and Maydeu-Olivares, 2011; Stark et al., 2011). Thus, this approach currently seems to be the most promising. In how far the coaching of test-takers might affect this technique remains to be seen, however.

Reasoning with the Test-Taker

Incorrect selection decisions based on personality self-ratings bear not only important implications for the person selecting but also the test-taker. Imagine an applicant who desperately wants a job and therefore, portrays a picture that is in large

agreement with the job profile but does not resemble the person's true personality. If the person gets selected, a behavior is expected that is atypical for the person. Thus, performing in the job will be either impossible or at least attached to high costs for the person. Arguments like these are often used to reason with test-takers not to fake. While first empirical evidence has shown that this might actually reduce faking on group level, the individual effects are mixed. Whereas some individuals do not fake at all, others fake just as much as without warning. Moreover, some test-takers are afraid of being accused of faking and actually lower their scores. Thus, on average the test score mean does not increase. The rank order, however, is greatly affected (Griffith et al., 2005). Thus, warnings seem to be no proper way to handle faking.

Conclusion

Within this article we first defined faking and put it in a nomological net of SDR. According to this, faking is an intentional and goal-directed behavior occurring due to an interaction between person and situation. Despite the mixed findings, recent research convincingly shows that faking does exist in real applicant situations. Its effects on a test score's validity are controversial and more research using job homogeneous applicant samples is needed. Nevertheless, the results so far at least suggest an effect of faking on ranking which in turn negatively affects selection decisions. A prereject selection procedure including multiple selection tools might offer a solution here. However, this approach might only work in situations where a large applicant pool can be drawn from. Measuring faking is also rather problematic so far. Overclaiming might be a promising approach considering existing research. However, correcting for faking on an individual level seems to be a long jump considering the current knowledge. More positive is the conclusion regarding the prevention of faking. Using pairwise preference models potentially offers a way to assess personality with self-reports free of faking influences.

On the whole the current overview provides an idea of a broad research field. The main ideas as well as conclusions are outlined and it should be clear that faking research still offers many potential breakthroughs and should continue to attract a large number of researchers.

Personality Assessment, Forced-Choice

Abstract

Instead of responding to questionnaire items one at a time, respondents may be forced to make a choice between two or more items measuring the same or different traits. The forced-choice format eliminates uniform response biases, although the research on its effectiveness in reducing the effects of impression management is inconclusive. Until recently, forced-choice questionnaires were scaled in relation to person means (ipsative data), providing information for intraindividual assessments only. Item response modeling enabled proper scaling of forced-choice data, so that interindividual comparisons may be made. New forced-choice applications in personality assessment and directions for future research are discussed.

Personality assessment is largely reliant on respondent–reported information. Objectively scored personality tests are perhaps the most widely used assessment mode. Such tests typically consist of multiple items, each intended to measure one personality trait. The most popular way of gathering responses on test items is by presenting them one at a time, as single stimuli ('single-stimulus' response format). Alternatively, two or more items at a time may be presented, forcing respondents to make a choice between them ('forced-choice' response format). Although appealing in many applications due to their ability to elicit finer differentiation between stimuli, forced-choice questionnaires have been controversial due to substantial scaling problems they pose. While it is easy to infer relative standings on different personality traits within one person, it has proven difficult to infer absolute trait standings for interpersonal comparisons from forced-choice data.

In this article, I consider first the different types of forced-choice formats, followed by a short discussion of their potential advantages in reducing response biases. I then turn to the measurement models that have been used to scale forced-choice responses, starting with the classical scoring model leading to ipsative scores, and followed by new model-based approaches based on item response theory (IRT). Models that have been applied to real-world forced-choice personality assessments are briefly described. Next, I evaluate the merits of different forced-choice questionnaire designs in providing accurate assessments of personality traits. Finally, I discuss the direction for future research with forced-choice measures in cross-cultural, educational, and industrial–organizational psychology.

Methods for Collecting Forced-Choice Questionnaire Data

Forced-choice data may be collected in many ways. Forced-choice questionnaires typically consist of multiple 'blocks,' presenting two or more items at the same time, and respondents are asked to indicate their preferences for the items within each block. Items within blocks may measure the same traits ('unidimensional' forced choice or UFC) or different traits ('multidimensional' forced choice or MFC). Table 1 summarizes the main types of forced-choice designs; each briefly described in this section.

Table 1 Methods for collecting forced-choice data

Block size	*Binary preference*	*Graded preference*	*Proportional preference*
$n = 2$	Paired comparison	Graded paired comparison	Proportional paired comparison
$n \geq 3$	Ranking; Partial ranking; Ranking with ties (Q-sort)		'Proportion-of-total-amount' task

Binary Preference

The simplest forced-choice task involves a pair of items, or block of size $n = 2$. Respondents are asked to indicate their preference for one item, for instance, to indicate which of the two statements is most true of them.

	Most true of me
A. I pay attention to details	X
B. I change my mood a lot	

When a block consists of three or more items ($n \geq 3$), respondents may be asked to rank statements according to the extent they are true of respondents, or to indicate the top rank only, or the top and bottom ranks, for example.

	Rank order	*Most/least true*	*Most true*
A. I pay attention to details	2		
B. I change my mood a lot	4	Least	
C. I have a good word for everyone	3		
D. I catch on to things quickly	1	Most	Most

Examples of assessments using forced-choice pairs are the Tailored Adaptive Personality Assessment System (TAPAS), the Navy Computerized Adaptive Personality Scales (NCAPS), the Edwards Personal Preferences Schedule (EPPS), and the Myers-Briggs Type Indicator (MBTI). Examples of tests using rankings are the Occupational

 http://dx.doi.org/10.1016/B978-0-08-097086-8.25084-8

Personality Questionnaire (OPQ32i and OPQ32r), the Personality and Preference Inventory (PAPI), the Customer Contact Styles Questionnaire (CCSQ 7.2), the Gordon Personal Profile Inventory (GPP-I), the Survey of Interpersonal Values (SIV), the DiSC Classic, and the Kolb Learning Style Inventory.

In ranking with ties, also known as Q-sort (Block, 1961), respondents have to assign items to categories, complying with a predefined distribution. For example, respondents are asked to sort 10 items into five piles, according to the extent to which the items describe respondents' personality, and only allowing a certain number of items in every pile:

Very untrue of me	*Somewhat untrue of me*	*Neutral*	*Somewhat true of me*	*Very true of me*
1	2	4	2	1
Number of items in pile.				

California Adult Q-Sort, Riverside Behavioral Q-sort, and Riverside Situational Q-sort are all examples of this format. Q-sorts are not rating tasks but pure forced choice, because assignments to categories are constrained so that respondents must perform direct comparisons between items. Even if no items are 'very true' of the respondent, he/she must assign the prescribed number of items to that category. The obtained responses are essentially rankings with ties – a group of items ranked first, a group of items ranked second, etc.

Assessments using paired comparisons and ranking tasks yield binary preference data, since the only information collected for any given pair of items is whether one item was preferred to the other or not. For full rankings, binary choices are known for every pairwise comparison; that is, in the example above, it is known that item A was preferred to items B and C, but not to item D. For partial rankings, such as those resulting from 'most/least' choices, some outcomes of pairwise comparisons are not known; for instance, it is not known whether item A was preferred to C or not. For rankings with ties, preferences for items within same category are not known.

Graded Preference

It is also possible to gather information on the extent of preference for one item over another. For example, we may ask respondents to indicate to what extent one statement is more (or less) true of them than the other using ordered categories.

	Much more true	*Slightly more true*	*Slightly more true*	*Much more true*	
A. I pay attention to details				X	B. I change my mood a lot

With this format graded (ordinal) preference information is available for every pairwise comparison.

Proportional Preference

To gather further quantitative information about the relative merits of items, respondents may be asked to distribute a fixed number of points between them. For instance, we may ask respondents to distribute 100 points among $n = 4$ statements according to the extent the statements describe them.

	Points (100 in total)
A. I pay attention to details	40
B. I change my mood a lot	0
C. I have a good word for everyone	10
D. I catch on to things quickly	50

This format captures yet more information about the extent of preference than graded comparisons. It is not only known, for example, that A was preferred to B more than it was preferred to C, but how much more. Proportions of the total amount are collected and therefore it may be inferred, for instance, that preference for A (40 points) was 4 times stronger than preference for C (10 points).

Advantages of the Forced-Choice Formats

Comparative judgments employed in forced-choice questionnaires can have substantial advantages over absolute judgments. First, forced choice makes it impossible to endorse all items indiscriminately (the so-called 'acquiescence' bias). It is also impossible to elevate or reduce ratings across all items ('leniency/severity' effects), or provide uniformly extreme or middle ground ratings ('extremity/central tendency' responding). Overall, the forced-choice formats eliminate any systematic response sets that apply uniformly across items (Cheung and Chan, 2002).

Second, forced choice tackles the problem with lack of differentiation in ratings (the so-called 'halo' effects). Halo effects are particularly problematic in personality assessments involving external raters (such as spouses, colleagues, or bosses) who often have overgeneralized perceptions of different characteristics of the assessment target based on one important dimension. Forcing choice between various characteristics of the assessment target facilitates finer nuances of judgment and reduces halo effects, enhancing the quality of data.

Third, binary preferences do not require any rating scales since items are compared directly. This is an advantage since test takers do interpret verbal and nonverbal anchors provided with the rating scale differently. Furthermore, Maydeu-Olivares and Böckenholt (2008) argue that comparing items directly may be cognitively simpler than rating them, particularly when there are many rating categories with few or poor verbal anchors.

Finally, the use of forced-choice formats in personality assessments has been largely motivated by attempts to reduce socially desirable responding. It has been thought from conception of forced-choice personality measures that

combining equally desirable items in the same block would reduce socially desirable responding compared to single-stimulus formats, where all desirable items can be easily endorsed and all undesirable ones can be rejected. Extreme forms of socially desirable responding, often referred to as 'faking good,' are particularly concerning in high-stakes personality assessments, where interest in the use of forced-choice questionnaires has been growing. Over the years, evidence for superiority of forced choice in high stakes (e.g., Christiansen et al., 2005; Jackson et al., 2000) as well as against it (Feldman and Corah, 1960; Heggestad et al., 2006) has been published. Findings are inconclusive for many reasons; including lack of control for differences in questionnaire designs and testing contexts as well as technical challenges in modeling forced-choice data (see Section Scaling of Forced-Choice Responses). Good methodology is essential to move this research forward, but most importantly, good understanding of test takers' cognitions when completing personality assessments in high stakes. While test takers' cognitions have been studied with single-stimulus measures (e.g., Robie et al., 2007), there is a clear gap in our understanding of such cognitions in forced-choice assessments.

Scaling of Forced-Choice Responses

While the forced-choice formats have been shown to eliminate or reduce many types of response biases, their use in personality assessment has been very controversial. The reason is that classical scoring methods, when applied to forced-choice questionnaires, yielded test scores inappropriate for interindividual comparisons. Recently, this problem has been overcome by the use of item response modeling.

Classical Scoring Model and Ipsative Scores

In the classical scoring scheme for single-stimulus items, more points are awarded to items that respondents endorse to a higher degree. The same logic has been applied to the forced-choice questionnaires. If item A is preferred to item B, it ought to be awarded more points. For instance, in a 'percentage-of-the-total-amount' task, the points that respondents award to items become item scores. Because all respondents have the same number of points to distribute, their total score for each block is the same (for instance, 100).

	Scale	*Person X*	*Person Y*
A. I pay attention to details	Conscientiousness	40	5
B. I change my mood a lot	Neuroticism	0	25
C. I have a good word for everyone	Agreeableness	10	60
D. I catch on to things quickly	Openness	50	10
Total		100	100

When the item scores are then added to make up scale scores, the total score (the sum of all scale scores) on a classically scored forced-choice test is the same for everyone. The same logic applies to classical scoring of all forced-choice designs. For example, in a 'most/least' partial ranking of four items, the most preferred item is given 2 points, the next two items are given 1 point each, and the least preferred item is given 0 points. The total amount of 4 points per block is the same for everyone, and the total score on the test is a constant.

This type of data is called 'ipsative' (from Latin 'ipse' – he, himself), because the scale scores are relative to self. Indeed, Person X in the example above obtained 50 points for Openness in one block, and this is his highest score in that block. However, because respondents have to indicate their preferences even if they agree with all items or disagree with all of them, this high score is the only high relative to other scores in the same block. It is possible that the absolute standing on Openness for Person X is in fact lower than that for Person Y, who only obtained 10 points for the same item. Ipsative scores are useful for intraindividual assessments because they provide valuable information of relative standings on personality traits for one person. They can be used in personal development, feedback, counseling, etc. They, however, cannot be used for interindividual comparisons.

The fact that the total score on the test is constant, despite different compositions of scale scores within that total for different people, causes substantial psychometric problems well described in the literature. As Clemans (1966), Hicks (1970), and others showed, ipsative scores cannot be analyzed in the same way as normative scores. The problems can be summarized as follows:

1. Ipsative scale scores always correlate negatively on average, even if the personality traits they measure correlate positively.
2. Ipsative scores cannot be factor analyzed using maximum likelihood method, because their variance–covariance matrix is of a reduced rank. Principal components analysis can be applied to ipsative scores; however, the results are difficult to interpret since the components tend to contain conflicting rather than convergent traits (Cornwell and Dunlap, 1994).
3. Ipsative scores distort criterion-related validity estimates since their correlations with any external measure must sum to 0, creating spuriously positive and negative correlations.
4. Internal consistency reliability cannot be applied since the assumption of consistent coding is not met in ipsative scores (Brown and Maydeu-Olivares, 2013).

Different remedies have been suggested to alleviate the impact of ipsative constraints in classical scoring. One such remedy is increasing the number of measured traits in forced-choice questionnaires using the MFC format. It has been argued that when 30 or so traits are assessed, interpersonal comparisons can be performed meaningfully (Baron, 1996). Another way of releasing the ipsative constraint is to present items indicating negative trait standings (for example, 'I miss important details') as well as items indicating positive trait standings (for example, 'I pay attention to details'). Selecting the former statement will take points away from the Conscientiousness score, and selecting the latter will add points. Hence, the total score will show some variation. However, because both types of items indicating Conscientiousness are scored relatively to items indicating other traits, variation of the

total score is still partially constrained (hence the name, 'partially ipsative' data). Partially ipsative data and ipsative data arising from MFC questionnaires measuring many traits are less problematic; however, their psychometric problems are not eliminated but merely reduced.

The troubles with ipsative data stem from the fact that the implicit scoring model bears no relation to the psychological process used in forced-choice judgments (Meade, 2004) – namely, relative positions on items are treated as if they were absolute positions. Adding relative positions of items together cannot possibly constitute a scale score that reflects person's absolute standing on a trait.

Item Response Modeling of Forced-Choice Questionnaire Data

To overcome the problems of ipsative scores, any scoring protocol for forced-choice data must consider the true meaning of item responses. To this end, the response process involved in comparative judgments must be modeled. There are many theoretical models for individual choice behavior. The oldest and the best known is the law of comparative judgment of Louis Thurstone (1927). Other influential models are Coombs' (1950) unfolding preference model, and Luce's (1959) choice axioms. These theories have been adopted for modeling of forced-choice questionnaire data; in addition, Luce's choice axioms have been applied by Andrich (1989) to provide explicit probability of binary choice.

IRT models for forced-choice questionnaire data can be classified according to three criteria: (1) block size that can be modeled, (2) dimensionality of comparisons (whether items measuring different traits can be modeled), and (3) the measurement model thought to underlie absolute judgments about questionnaire items.

Two types of measurement models have been utilized in forced-choice modeling: linear factor analysis models and ideal-point models. Linear factor analysis models assume that person p's tendency to endorse item i (psychological value or item 'utility,' as named by Thurstone) measuring personality trait a is a linear function of his/her trait score. (LFA models allow items measuring multiple traits; a special case of factorially simple items is given here for simplicity.)

$$\text{utility}_{pi} = \text{mean}_i + \text{loading}_i \text{trait}_p^a + \text{error}_{pi} \qquad [1]$$

The factor analysis model assumes that for items indicating positive trait standings (for example, 'I pay attention to details,' indicating Conscientiousness), the item utility will increase as the trait score increases. For items indicating negative trait standings (for example, 'I miss important details'), decrease in item utility is expected with an increase in trait score. This so-called 'dominance' model is a fair representation of response process for most personality items that tend to represent extreme positive or negative standings on personality traits.

Ideal-point models assume that person p's utility for item i measuring trait a is a function of distance between his/her trait score and the item location. (There are many forms of ideal-point models; an expression using the unweighted Euclidean distance is given here without loss of generality.)

$$\text{utility}_{pi} = \text{mean}_i - \left|\text{trait}_p^a - \text{location}_i\right| + \text{error}_{pi} \qquad [2]$$

This family of models assumes that items and people can be placed on the same trait continuum. Each item represents some position on the trait and can be thought of as an 'ideal' item describing characteristics of persons with this level of the trait (hence the name 'ideal point'). For instance, item 'My paperwork is always in order' represents a very high Conscientiousness score, and item 'My attention to detail is about average' represents an average score. For the latter item, the relationship between the item utility and Conscientiousness trait is clearly not linear, because the utility for this item will peak around the average Conscientiousness score, and be lower for respondents with either high or low scores. The ideal-point response process was originally proposed for attitude measurement, but recently has been suggested for use in personality assessments (Drasgow et al., 2010).

Thurstonian IRT Model

Scope

Brown and Maydeu-Olivares (2011) developed the Thurstonian IRT model to enable analysis of data arising from forced-choice tests measuring multiple traits with ranking blocks of any size. Item parameters, correlations between the latent traits, and person trait scores can be estimated using this IRT model.

Items in each block may measure the same trait (UFC) or different traits (MFC), or any combination of the two. A linear factor analysis model is assumed to describe the relationship between the items and traits they measure (i.e., the model utilizes the most common type of personality items, dominance items).

Origins

This model is based on Thurstone's (1927) law of comparative judgment. Thurstone postulated that preference judgments are determined by utilities of items under comparison. Each item elicits a utility judgment (judgment of the item's psychological value), and person p will rank item i above item k if his/her utility for i is higher than for k:

$$\text{prefer item} \begin{cases} i & \text{if} \quad \text{utility}_{pi} \geq \text{utility}_{pk} \\ k & \text{if} \quad \text{utility}_{pi} < \text{utility}_{pk} \end{cases} \qquad [3]$$

Observed rank orders of items within a block, therefore, can be seen as manifestations of the order of corresponding item utilities. To describe the observed ranks in a block, all pairwise comparisons between items are considered. There are $n(n-1)/2$ nonredundant pairwise comparisons in a block of size n. For example, any given rank order of four items, A, B, C, and D, is fully described by knowing outcomes of six paired comparisons: {A, B}, {A, C}, {A, D}, {B, C}, {B, D}, and {C, D}. For any of these six pairwise comparisons, the utility maximization rule [3] applies.

Model

Because preference for item i over item k is determined by the difference of their utilities, the utility difference is the central unit of analysis in Thurstonian modeling. To model responses to ranking blocks in relation to personality traits the items measure, Brown and Maydeu-Olivares (2011) assumed that

person's utilities for items relate to the traits via a linear factor analysis model. Thus, the utility differences can be expressed as linear combinations of personality traits using [1]. Observed binary preferences are thought to be dichotomized expressions of unobserved utility differences. With this, the probability $P(y_{p\{i,k\}} = 1)$ of preferring the first item in a pair $\{i,k\}$ of items measuring different traits a and b, conditional on person p's trait score is given by the cumulative standard normal function.

$$P(y_p\{i,k\} = 1) = \Phi\left(\frac{-\text{threshold}_{\{i,k\}} + \text{loading}_i \text{trait}_p^a - \text{loading}_k \text{trait}_j^b}{\sqrt{\text{var}(\text{error}_i) + \text{var}(\text{error}_k)}}\right) \quad [4]$$

For items with positive factor loadings, the probability of preferring item i to item k increases when the score on the trait measured by item i increases and the score on the trait measured by item k decreases. The response function [4] defines a surface, an example of which is presented in **Figure 1**, where the probability of preferring one item to another is plotted against two traits. The surface illustrates that the dominance process of evaluating individual items results in a monotonic relationship between the person's trait scores and the choice probability.

When items measuring the same trait are being compared in a forced-choice block, the conditional probability of preferring item i to item k by person p [4] simplifies to

$$P\left(y_{p\{i,k\}} = 1\right) = \Phi\left(\frac{-\text{threshold}_{\{i,k\}} + (\text{loading}_i - \text{loading}_k)\text{trait}_p^a}{\sqrt{\text{var}(\text{error}_i) + \text{var}(\text{error}_k)}}\right) \quad [5]$$

It follows from [5] that two items with similar factor loadings measuring the same trait will yield a pairwise comparison with a near-zero pairwise factor loading; thus it provides very little information for measurement of the latent trait. In other words, items that are likely to have very similar valuations by the same person are ineffective as a pair for determining the absolute standing on the trait. This is a fundamental property of comparative judgments rather than of a specific model; this feature is shared by all forced-choice models, as the reader shall see.

The unidimensional response function is a curve, examples of which are presented in **Figure 2**. The figure illustrates that two items with very different factor loadings yield a highly informative comparison, whereas two items with very similar factor loadings (albeit highly discriminating in their own right) yield an uninformative comparison.

To enable parameter estimation, the pairwise preference model [4] is embedded in a generalized Structural Equation Modeling (SEM) framework. Responses to all ranking blocks (coded as binary outcomes of pairwise comparisons using [3]) are modeled simultaneously, each outcome serving as an indicator of common factors (latent personality traits), resulting in a single measurement model with binary outcomes (IRT model). The model takes care of dependencies that exist in blocks of size $n > 2$, where pairwise comparisons involving the same item share the same factor loading and the same error term. The model estimates item parameters according to [4] – factor loading and error variance for every item, and threshold for every pairwise comparison. In addition, correlations between the latent traits are estimated.

Figure 1 Example Thurstonian IRT response function for a pair of items measuring two different traits.

After the item parameters have been estimated, person trait scores can be estimated by either maximum likelihood method or Bayesian estimation. It has been shown that Thurstonian item response modeling approach overcomes the problems of ipsative data (Brown and Maydeu-Olivares, 2013).

Applications

Applications of this flexible model have included reanalysis of existing forced-choice questionnaire data and development of new measures. Reanalysis of the CCSQ demonstrates the advantages of IRT modeling for personality assessment; specifically, interpersonal comparability of person trait scores estimated by the IRT method as opposed to the classical method resulting in ipsative scores (Brown and Maydeu-Olivares, 2013). The development of a new IRT scored version of the Occupational Personality Questionnaire (OPQ32r) illustrates how Thurstonian IRT modeling may be applied to reanalyze and redevelop an existing assessment tool, enhancing its strong features and transforming its scoring protocol (Brown and Bartram, 2009). The Thurstonian IRT model was also used to inform the development of a new measure, the Forced-Choice Five Factor Markers (Brown and Maydeu-Olivares, 2011).

Zinnes–Griggs Model for Unidimensional Pairwise Preferences

Scope

Zinnes and Griggs (1974) developed an IRT model to enable analysis of data arising from forced-choice tests consisting of simple paired comparisons (block size $n = 2$) of items measuring the same trait (UFC). Item parameters and trait scores for individuals can be estimated using this IRT model. An ideal-point process is assumed to describe the relationships between test items and the trait they measure.

Figure 2 Example Thurstonian IRT response functions for two pairs of items measuring the same trait.

Origins

This model is based on Coombs' (1950) preference decision theory. According to Coombs, when facing a choice between two items, the person will prefer the item closer to an 'ideal' item representing own position on the trait ('ideal point'). Formally, given a choice between items i and k, each with their own location on the trait, person p will

$$\text{prefer item}\begin{cases} i & \text{if} \quad |\text{trait}_p - \text{location}_i| \leq |\text{trait}_p - \text{location}_k| \\ k & \text{if} \quad |\text{trait}_p - \text{location}_i| > |\text{trait}_p - \text{location}_k| \end{cases} \qquad [6]$$

Coombs' model implicitly assumes an ideal-point response process for every item involved in comparison; that is, the psychological value or utility of an item to a person equals the inverse of the distance between the person trait score and the item location. Because of this inverse relationship between the distance to an item and the person's utility for it, Zinnes and Griggs called the item-person distance 'disutility.'

Model

Zinnes and Griggs (1974) modified the original deterministic version of Coombs' decision model to make it probabilistic. To this end, they consider 'noisy perceptions' of item locations and the person's own ideal point at the time of comparison – three random variables distributed normally around their expected values. They showed that the probability $P(y_{p\{i,k\}} = 1)$ of preferring the first item in a pair $\{i,k\}$ of items measuring the same trait, conditional on person p's trait score is a one-dimensional IRT model, where $\Phi(\cdot)$ is a cumulative standard normal distribution function:

$$\begin{aligned} &P\left(y_{p\{i,k\}} = 1\right) \\ &\quad = 1 - \Phi\left(a_{p\{i,k\}}\right) - \Phi\left(b_{\{i,k\}}\right) + 2\Phi\left(a_{p\{i,k\}}\right)\Phi\left(b_{\{i,k\}}\right) \end{aligned} \qquad [7]$$

where $a_{p\{i,k\}} = (2 \cdot \text{trait}_p - \text{location}_i - \text{location}_k)/\sqrt{3}$; $b_{\{i,k\}} = \text{location}_i - \text{location}_k$.

In this simple model, the conditional probability depends only on the person's trait score and the item locations. It is therefore assumed that items vary only in their locations on the trait continuum, and thus they are equally good measures of the trait (equally discriminating).

An example response function is illustrated in Figure 3, where the conditional probabilities of preferring the first item in a pair are plotted for two pairs of items, with different combinations of item location parameters. This figure shows that comparing items with similar locations results in a very 'flat' function with a shallow slope; and comparing items with very dissimilar locations results in a function with a steep slope. Therefore, comparisons between items located closely on the same trait are noninformative. The same effect is observed when items with similar factor loadings are compared under the Thurstonian IRT model (see Figure 2).

Applications

This straightforward unidimensional model has been applied to create the NCAPS.

Multi-Unidimensional Pairwise-Preference Model

Scope

Stark et al. (2005) developed the Multi-Unidimensional Pairwise-Preference (MUPP) model to estimate person trait scores from binary paired comparisons (block size $n = 2$) of items measuring the same trait (UFC) or different traits (MFC). Currently, item parameters cannot be estimated from the actual forced-choice data and are assumed known. The MUPP model assumes an ideal-point response process for the items involved in comparisons.

Origins

The MUPP model adopts an approach to explaining preference judgments originally suggested by Andrich (1989). Andrich's motivation was to write an explicit expression for the

Figure 3 Zinnes-Griggs response functions for two pairs of items measuring the same trait.

probability of preferring one item to another through probabilities of accepting and rejecting the individual items. First, he postulated that the event of picking item i from the set $\{i,k\}$ has the same probability as the event of picking the first of two alternatives: (1) endorsing i and rejecting k, or (2) endorsing k and rejecting i.

Second, Andrich assumed that acceptances and rejections of individual items are independent events, conditional on the traits the items measure; therefore the joint probability of endorsing i and rejecting k is the product of two probabilities, the probability of endorsing i and the probability of rejecting k. With this, the probability $P(y_{\{i,k\}} = 1)$ of preferring the first item in a pair $\{i,k\}$ of items measuring different traits a and b, conditional on person p's trait score is given by

$$P\left(y_{p\{i,k\}} = 1\right) = \frac{P\left(\text{endorse } i \middle| \text{trait}_p^a\right) P\left(\text{reject } k \middle| \text{trait}_p^b\right)}{P\left(\text{endorse } i \middle| \text{trait}_p^a\right) P\left(\text{reject } k \middle| \text{trait}_p^b\right) + P\left(\text{reject } i \middle| \text{trait}_p^a\right) P\left(\text{endorse } k \middle| \text{trait}_p^b\right)} \quad [8]$$

If items measuring the same trait are compared, the MUPP gives a response curve similar to those depicted in Figure 3. Just like under the Zinnes–Griggs model, comparisons between unidimensional items with similar locations are noninformative, and the same effect is observed when items with similar factor loadings are compared under the Thurstonian IRT model (see Figure 2).

Applications

The MUPP model was used in the development of the TAPAS, a comprehensive and customizable assessment system measuring any subset of 23 personality facets deemed important for predicting job performance in civil and military organizations.

Model

Stark et al. (2005) use an ideal-point model to substitute the probabilities of accepting and rejecting individual items in general expression [8]. Specifically, they advocate the use of a binary version of the Generalized Graded Unfolding Model or GGUM (Roberts et al., 2000). The GGUM is very flexible and allows items to differ in discrimination, locations, and even in maximum probability of endorsement.

If items measuring different traits are compared, the item response function [8] in conjunction with the binary GGUM defines a surface, an example of which is presented in Figure 4. This surface is rather complex, with the ideal-point process of evaluating individual items resulting in a nonmonotone relationship between the latent traits and the pairwise preference.

McCloy–Heggestad–Reeve Unfolding Model for Multidimensional Ranking Blocks

Scope

McCloy et al. (2005) sketched a model for the process of responding to MFC blocks of any size, compiled from ideal-point items, to inform item selection and estimate person trait scores. Item parameters cannot be estimated from the actual forced-choice data and are assumed known.

Origins

This approach adopts an extension of Coombs' original one-dimensional unfolding model to the multidimensional case. The model predicts that a person will prefer an item that is located nearer to the person in multidimensional trait space than another item located further from the person in that

Figure 4 MUPP response function for a pair of items measuring different traits.

space. The use of Coombs' unfolding decision model implicitly assumes the ideal-point response process for every item involved in comparisons, each reflecting changes in its own personality trait.

Model

Items are assumed to be equally good measures of the traits (equally discriminating); therefore the only differentiating feature for items is their locations. This and another simplifying assumption – that of no random influences on preference decisions – are used to inform creation of forced-choice designs that are effective for accurate estimation of trait scores. McCloy and colleagues show that assuming item locations known, an effective forced-choice measure can be assembled from blocks of items with locations that vary across the attribute space.

Discussion

Since conception of forced-choice personality measures, the biggest technical challenge was scaling of person's relative preferences to reflect their absolute standing on traits of interest. Classical scoring methods that simply counted the relative responses as absolute did not provide adequate measurement, making the forced-choice assessment method controversial. Modern scoring methods have the potential to provide proper scaling by taking to account the comparative nature of judgments. These methods link observed comparative decisions to unobserved personality traits, controlling for properties of items.

Despite the breakthroughs in scaling forced-choice questionnaire data, not every forced-choice design is guaranteed to deliver good measurement properties once an IRT model has been applied to it. Just like a single-stimulus questionnaire with poor items that do not provide information on target traits or with a poor rating scale, a forced-choice questionnaire may be incapable of providing accurate measurement of target traits whichever modern scoring model is applied. This is because the forced-choice format dictates its own rules of measurement.

One such rule was demonstrated in this article – comparisons between items that are likely to elicit similar value judgments in the same person are not informative for establishing the absolute trait position. For example, two items, 'My paperwork is always in order' and 'I am always on top of my paperwork,' may be good measures of Conscientiousness in their own rights, but when put in a paired comparison, they will provide no information on the Conscientiousness trait. This is because high scorers will agree with both items and will be forced to make a random choice between the two. Low scorers will disagree with both items and will again make a random choice. The same will happen for any given standing on the trait – the trait score will have no effect on the preference decision, with the random error playing the largest part. No IRT model, whether utilizing dominance items or linear factor analysis items, will be able to recover the absolute position on the trait in this situation. This is the fundamental property of comparative judgments, not of any specific model.

More generally, items that elicit similar utilities, using either the dominance process or the ideal-point process, are ineffective in forced-choice blocks. This is why comparing items measuring highly correlated traits is not effective, and combining items with factor loadings of opposite sign (measuring the positive and the negative extremes of positively correlated traits) may be necessary (Brown and Maydeu-Olivares, 2011). The same conclusions follow when ideal-point items are utilized in multidimensional forced choice – items with very different locations on traits are required (McCloy et al., 2005).

There has been much debate about relative merits of dominance and ideal-point items as utilized in forced-choice measurement (e.g., Drasgow et al., 2010; Brown and Maydeu-Olivares, 2010). However, it is becoming clear that all models for forced-choice are essentially similar; they model the same process, which has its own fundamental properties. The successful applications of both types of models in personality assessment show that neither dominance nor ideal point family model is inherently superior for forced-choice measurement. Rather, the choice of model must be dictated by the nature of items used. If items that elicit the ideal-point response process are used (because they deemed more appropriate on conceptual grounds), an ideal-point forced-choice model is appropriate. If items that elicit dominance responses are used, a linear factor analysis forced-choice model is appropriate.

Finally, it is worth noting that all the existing IRT models are choice models; that is, they are suitable for modeling binary preference data (i.e., paired comparisons, rankings, and partial rankings). Although extensions to ordinal or proportional preference data are possible within the generalized SEM framework adopted by Thurstonian modeling, these are yet to establish themselves in forced-choice personality assessment. Such developments would open doors for proper scaling of Q-sorts and questionnaire employing 'proportion-of-total-amount' tasks.

Conclusions and Directions for Future Research

The main objective of personality assessment – differentiating people in relation to traits of interest – can be achieved by collecting either absolute judgments or comparative judgments. In respondent-reported assessments, absolute judgments can be subject to numerous response biases, such as idiosyncratic uses of rating scales, unconditional agreement with statements as presented (acquiescence), lack of differentiation (halo effects), and others. Forcing choices between questionnaire items can help eliminate any effects acting uniformly across items. Reducing nonuniform effects, such as differential inflation of scores on traits deemed important in specific contexts ('faking good'), with forced-choice formats is proving more challenging. More research is needed to understand the motivated distortions to forced-choice questionnaires in high-stakes personality assessments. With rapid development of item response modeling approaches, we are well placed to tackle this challenge.

Even before the advent of item response modeling in the forced-choice assessment space, ipsative and partially ipsative scores demonstrated similar or even enhanced criterion-related validities compared to single-stimulus measures (Bartram, 2007; Salgado and Táuriz, 2014). This improvement is presumably due to reduction in response biases detrimental to validity. The psychometric problems of ipsative scores, however, should not be underestimated as they can result in spuriously significant validity coefficients (Brown and Maydeu-Olivares, 2013). It is my belief that conclusive validity evidence for forced-choice assessments can only be gained by using model-based measurement. With increasing repertoire of properly scaled forced-choice measures, there is much to look forward to in this area of research.

Recent developments in item response modeling have enabled the use of forced-choice personality assessments without the downsides of ipsative data. The potential reduction in response biases that forced-choice measures can provide, while maintaining interpersonal comparability of trait scores, is an exciting prospect for many applications in personality assessment. For instance, cross-cultural personality research, where culturally specific response sets present a challenge for score comparability, could benefit from the use of direct comparative judgments. Assessments by external raters, whether in workplace, health, or education, could also benefit from the use of carefully designed forced-choice questionnaires to enhance validity by reducing rater effects such as halo and leniency/severity. Provided that appropriate methods are used to design and score such assessments, the forced-choice formats can be a viable alternative to the single-stimulus formats.

Abstract

This article looks at different essential methods to assess personality and individual differences. It considers a simple but robust selection model, which includes selecting *out* and selecting *in* people at work. It then goes on to consider current trends and recent developments in the area. The main part of this article considers, in more detail, the advantages and disadvantages of the standard methods like interviews, references, biodata, and tests. The final part of the article concerns addressing 12 myths concerning psychometric testing in general.

Introduction

There is a great deal of interest and research into assessing people at work. Assessment can be formal and informal; based on test data or personal intuitive judgments; with more or less serious consequences. Many people invest a large amount of time and energy in assessing others which they believe is a good investment.

Assessing people at work is important for many reasons. The most important is the cost benefit analysis: *the benefits of the right decision* over *the costs of getting it wrong*. In other words, there are great financial benefits for hiring a positive and productive person; and many costs, especially financial, to hiring an unhappy, unproductive, and difficult person.

Using good assessment tools has other benefits: it can 'up-skill' managers who use various tools and techniques and *increase their psychological mindedness*. It also has a major benefit for the interviewee as feedback can considerably *increase their self-awareness*. Further, if a test is used widely in an organization people can often have a *useful shared language* to discuss issues in terms of psychological profiles and preferences.

The question for assessors is essentially *what to assess, who is best suited to do it, when and why*. To some extent the 'what' can neatly be divided into three areas.

What a person can do? This refers to their *ability*. It is about their capacity to do various tasks efficiently given that they have the desire to do so. It also refers to their ability to learn new tasks. Assessing what a person can do is more often measured by cognitive ability (intelligence) and skills tests though it may also be useful to assess creativity as well as the ability to lead others.

What a person will do? This refers to a person's *motivation* or what they want to do. Motivation refers to a person's values and drives. Everyone can be persuaded to do things as a function of rewards and punishments but this refers to what a person will do on an everyday basis without strong rewards or punishments trying to shape behavior.

What a person wants to do? This refers to preferences/*personality* for certain activities over others. It is about what a person likes to do and will do so freely without any form of coercion. It is about their values and personality and motivation which pushes them in one direction or another.

Assessors need to know all three things about a person they are assessing.

The Essential Methods

There are, in essence, mainly five different methods to collect data on people. Of these the first three are most commonly used.

Self-Report

This is essentially what people say about themselves in interviews (both structured and unstructured); in self-report personality and other preference tests; and on their CV (personal statement or application form). These are very common ways of assessing people and they nearly always want and expect an interview when they can answer questions and talk about themselves.

There are however two major problems with self-report. *The first is called under various names like dissimulation, faking, or lying*. It concerns people giving false information, or embellished information about themselves. This behavior has been broken down by psychologist into two further types of behavior.

Impression Management

This is where the person attempts to create a good impression by leaving out information, adding untrue information (errors of omission and commission) as well as giving answers that are not strictly correct but, they hope, create a good impression in the interviewer's mind. This is done consciously and is very common. Indeed, it is expected in the answer to some questions but it can be very serious when, for instance, people claim to have qualifications or experiences they have not had, or leave out important information (about their health, criminal past).

Self-Deception

This occurs when a person, in their own view answers honestly, but what they say is untrue because they lack self-awareness. Thus they might honestly believe that they are a 'good listener' *whereas* all the evidence from reliable sources is that

this is not true. This can occur for both good qualities (cognitive and emotional intelligence) as well as weaknesses (impulsivity, depression). People with low self-awareness often self-deceive.

The way personality and other preference tests attempt to deal with this issue is to use Lie Scales in the test. These go under various names (validity, dissimulation) and many exist. They are generally known as measures of response bias.

The second is about self-insight. This is primarily concerned with what people cannot say about themselves even if they wanted to. This is best seen with issue around motivation where people cannot, rather than will not, give honest answers about the extent to which they are motivated by power, recognition, money, or security. Indeed motivation is one of the most difficult topics to accurately assess, and yet, for business people, though as among the most important.

One way psychologists have tried to deal with this issue is projective techniques such as the Thematic Apperception Test, or various sentence completion tasks. For instance, a person may be asked to complete the following sentence: "My greatest regret is…"; "At work I often appear to be…"; "My parents would be most proud of my…" The idea is to content analyze these responses to detect themes. These methods are expensive in terms of time and unreliable meaning too many minor factors (like their mood and where the interview takes place) affects their response. They remain 'unproven' for most psychometricians.

Observation Data

This is what other people say about an individual in references and testimonials; 360 ratings (multisource feedback) and appraisal and other performance management data. Most organizations attempt to get reliable reports from other people who know the candidate that they are attempting to assess. Many application processes ask candidates to list people who know them well in some salient setting and may be called upon.

There are also problems with this type of data. The first is *the* 'data bank' *of the observer*. This essentially means what information the observer has about the candidate. Thus a boss has a different data set than a colleague or a subordinate. A school teacher or university lecturer will have a different data set than an employer. The question is *what they know*: the quality, and quantity of data on a person's ability, motivation, work style, etc.

The second issue is the extent to which they are prepared to *tell the truth about an individual.* Some organizations refuse staff to write references because of litigation. They can be taken to court for what they did say or did not say. They are told all they can say is that "X worked here from dates A to dates B." People sometimes have a vested interested in 'talking up' a person they want to leave, or else they do not disclose important aspect about an individual's work history such as accusations of inappropriate behavior.

People also choose their specific, favorite referees because they hope that they will be very positive. There seems to be an etiquette with respect to what people write or rate on references. Many know the power of negative information and therefore try strongly to resist providing any negative information. It is therefore rare to get very accurate or useful data on a person's weaknesses or challenges from references.

Test Performance

This refers to how well people do on tests: power, timed, ability tests. These are of *maximum performance*. There are also preference, untimed, personality tests which are *of typical performance*. There are also behavioral tests, which measure actual observed and measured behavior often in groups.

There are thousands of tests of many types to choose from. Most professionals only know about a smaller number. They also are often not clear about why one test maybe psychometrically better than another. This is nearly always a question of evidence of the psychometric properties of the test. Tests differ enormously. Some require a one-to-one administration, others can be easily and effectively be run in largish groups. Some are 'objective' versus open-ended tests: the former requires the choice of several responses; the latter means one has to generate the response.

Physiological Evidence

This is probably the newest and most disputed of all measures. Thus for some jobs, employees have to go through a '*medical checkup*' which they may have to do on a regular (i.e., annual) basis simply to keep their job. This would be true of such jobs as being an airplane pilot. In other jobs, for instance, working in the alcohol industry, it maybe a requirement that people go through a *liver function test.* Simple blood tests and saliva samples can be used for various diagnoses including drug taking and stress levels. Everyday it seems new simple physical measures are being devised that are claimed to be able to detect such things as whether a person is more likely to get a debilitating mental or physical disease.

Personal History/Biography

This refers to person's personal history, for instance, where they were born and educated; the family from which they came;' and their present family and address. Some information is thought to be very important such as what was the social class of the parents; does the person come from a minority race or religious group; how many brothers and sisters do they have and what is their place in the birth order; what was their schooling like and how successful were they at it.

This area is called biodata. It aims to determine, through empirical methods the biographical markers of success in very particular jobs. It has limitations which will be discussed later.

A Simple Selection Model

Below is the simplest selection model. The aim is to select the good and reject the bad candidates. Through job analysis selectors usually have a list of competencies that they are looking for. However there are two problems with this model. First, the assumption of linearity: this is the idea that more is better. The more you have of a quality (intelligence, creativity, integrity) the better. For most jobs you need an optimal

amount rather than a maximal amount. Second, the failure to select out: that is to actively look for things that you do not want in the person being assessed.

	Good	*Bad*
Select	A	B
Reject	C	D

In this model, B and C are errors. Everyone is concerned with getting A but nobody with D.

The more important the job and the more the consequences of failure or derailment count, the more important it is to seek assess potential derailers.

Recent Developments: What Is Hot and What Is Not

There are a number of new definable products, trends, and developments in the area. These are driven by various different forces.

First, there are *changes in the law*: legal changes and litigation risks have driven some issues (e.g., integrity testing, diversity training). Second, there are *changes in business*: as many organizations attempt become more flexible and competitive they become concerned with specific assessment-related issues, e.g., in spotting and managing talent; in strengthening leadership; in managing restructuring, acquisitions, and mergers. Third, there are the *ideas of gurus (business writers)*: popular books highlight various concepts, issues, and methods, some of which are enthusiastically embraced by business people (e.g., emotional intelligence). Fourth, there are the *recommendations of consultants/academics*: they often have their own agenda, which might or might not be related to the above.

Thus it is possible to see the emergence of various concepts, products, and measures used to assess people for jobs and to develop them. Further just as some of these products begin to emerge others tend to wane. Thus, 360° evaluation/feedback is currently probably at its zenith but it now much less popular than it has been. Equally, outward bound/outdoor training to strengthen teamwork seems on the wane.

Other factors have also played a part in developments in this area. First, *labor market shortages*: Shortages across Europe have led many companies to rethink their strategy and process to ensure it is fair to all concerned and that they can attract and correctly identify talented individuals. Second, *technological developments* and two issues are relevant here: The administration of tests via computers as well as recruitment and testing online via the Internet. Third, *applicant perceptions* which refers to the perceptions of applicants as to the fairness and validity of the assessment process. This is, in part, not only an impression management task for all organizations, but also refers to the effect of assessment methods on job acceptance and subsequent performance. Fourth, *construct-driven approaches* which refers to being clear about what one is trying to assess and why. That is having a theory and evidence for the factors/constructs that one is trying to assess and show their predictive validity.

There have been very specific developments and various trends are noticeable. There have been many advances in new data tools. For instance, there are now new *interactive tests* where people respond to carefully prepared video/acted scenes on a computer. These can even be delivered using mobile devices. They can be adapted for very specific company uses. One of the newest, but as yet untested ideas is the use of Avatars in assessment situations. There is now more and more interest in samples of real-life behavior sometimes called 'thin slides' whereby people make accurate judgments of real-life behavior perhaps recorded by video. There is an increased interest on the test-takers experience and reactions. Most organizations are aware of the limitations of the traditional interview and are making efforts to introduce well structured, panel interviews. Poor validity response rates and litigation issues have meant the traditional reference is being replaced by structured telephone calls asking specific questions of targeted interviewees (often peers).

There is now great emphasis on the power and usefulness of peer and subordinate ratings for assessment purposes. This has been a major consequence of an interest in 360° multirater feedback work. Organizations are being very sensitive to the possibility of bias (sex, race, language) in ability tests. They are also particularly concerned that they have face validity for candidates. There is always the development of tests to measure new (faddish) constructs, e.g., spiritual intelligence, practical intelligence. Psychometric tests continue to be developed in large numbers and put on the market. Some clearly 'chime with the spirit of the time' like tests of *emotional intelligence*. Biodata, psychomotor tests, and tests of job knowledge are *not* frequently used. They have however never disappeared and remain the favorite of particular clients in very particular settings.

The concept of using work-samples and probation periods appears to be gaining more attention. Probation periods if strictly enforced give both parties (employer and employee) a chance to revisit their decisions. Assessment Centers remain the basis of many organizations' preferred methods. They are very expensive and time consuming but recognized as the best. Most are designed very specifically for each company and there particular requirements. There is a great interest in assessing 'people with potential' or 'highfliers' but people are not sure how to do it. Organizations differ widely to whether they should bring assessment expertise in-house or outsource all or some of it. Much less interest and expertise is devoted to assessment for development purposes. This is done through mentoring and coaching which may or may not involve some formal assessment procedures. Organizations are beginning to realize that they can cost the effectiveness of successful assessment/selection in monetary terms which can have important implications.

Assessment Methods

A primary issue in the field of assessment is the wide choice of method to use – ranging from the informal to the highly technical.

The Interview

There are many variations on the job interview: How long they last; how many interviewers they have; whether they are

panel/board interviews; and most importantly whether they are structured or not?

Do different interviewers agree? That is what is the interrater/observer/judge's reliability? The answer is about $r = 0.50$ and better as to their reliability and validity in *structured* interviews. Validity is however much lower. For structured interviews it is about the same for one-to-one versus board interviews ($r = 0.35$) but for unstructured interviews the one-to-one ($r = 0.11$) is about half as good as board interviews ($r = 0.21$). This means that interviewers of the same person do not agree very much on their assessments *and* that these assessments are not very useful predicting success (or failure) on the job. Only planned, structured interviews offer good data to really be useful in assessment.

Why are interviews so poor at predicting performance? There is a long and growing list of factors that collectively explain this. Interviewers differ in insight, skills, preferences. They differ in motives, attention, and need for justification of their decisions. Interviewees often try hard to manage a positive (not totally realistic) impression by self-promotion and self-enhancement. Interviewees are also increasingly being self-coached on how to behave in interviews. Put simply, interviewees (and interviewers and referees) tell lies of omission and commission. There are many and systematic variations in how interviewers use the rating scale.

There is also range restriction in ratings meaning that raters never use the full scale particularly the two ends. They do not discriminate/differentiate clearly enough between the different candidates. Too often interviewers make up their mind before the interview. Interviewers, like everyone else are susceptible to forming a first impression and ignoring later data. More importantly we know that reasons to reject (i.e., select out) factors have disproportionate weight compared to select-in factors. Finally many interviewers have their own (wrong, unproved, bizarre) implicit personality theories (i.e., red heads are intelligent, rugby players are good team workers).

Interviews can be improved to increase their reliability and validity by various relatively simple steps. These are very important to make the ever-popular interview a useful assessment method. Select, where possible good, insightful, natural interviewers. Always use more than one interviewer in panel or board interviews and use the same interviewers throughout the process. It is important to train interviewers in the fundamental skills of interviewing and ensure that they take notes to help memory and settle arguments.

Personal References

References are usually free response or ratings that an observer reports on another. That is they are observation by an individual known to the candidate. Though cheap and popular they are thought of as unreliable and of poor validity. There are three main reasons given for their poor reliability. First, *leniency*: Most references are indiscriminately positive. This is for three reasons. Candidates choose themselves those they know are most likely to be very positive; respondents worry negative evaluations may result in a libel suit; respondents have no incentive to take the time or tell the truth. Second, *idiosyncrasy:* People can and do use idiosyncratic language, examples and criteria to describe and evaluate others. Third, *free-form references*: Reference writers are often offered no guidelines in what they are required to do. They can offer long/short, descriptive/evaluative, and relevant/irrelevant data.

It is possible to improve the validity of the reference by explaining fully the purpose of the reference, using rating scales or a forces choice format. Using well-designed rating scales also helps a great deal.

The data also suggest that *peer* ratings are the most useful, valid, and reliable. Referees are best when the employer chooses the referees; those referees are peers who know the candidate well; the referees are asked specific questions and are guaranteed anonymity. Switching to the Internet has been argued to provide quicker, cheaper selection and assessment with wider access for many people. It saves time and travel costs, even leading to the possibility of 'same day offers.'

Organizations thus now make job offers (recruitment advertisements) on their Web site. Electronic application forms can be used to collect data and do a simple first-filter. Those without certain qualifications may quickly be rejected; software can be written to do a matching task between answers to questions and the 'ideal' profile. However, still not everyone has access to the Internet. There are age, educational, ethnicity, income, and gender correlates of those with and without access. This has legal implications. Electronic media do not bypass paper-based problems like faking (social desirability) both impression management as well as omissions and commissions. Also, sifting is fast but many still only look for keywords, thus it may be no more reliable and accurate.

Overall the new assessment technologies (predominantly the Web) have specific goals: improve efficiency, enable new screening tools, reduce costs, standardize the HR system, expand the applicant pool, promote the organizational image, increase applicant convenience.

However there are also unintended effects. The use of the Internet does expand the applicant pool but also increases the number of underqualified and out-of-country applicants. It is easy to be *flooded with inappropriate applicants*. There is also the *loss of personal touch* that both assessor and assessee value and respect. There are also concerns about *cheating* if tests are used. Finally there are still concerns about *adverse impact* for organizations when certain groups simply do not have access to the technology.

HR technology remains a challenge. The hopes of individuals have been both very high and not all the experiences have been positive. But it seems to be the future. Internet advertising and recruitment seems very cost-effective. Young people expect it.

Biodata

This is a method of scoring biographical factors. It makes the assumption that the past predicts the future and that certain life experiences at and before work have predictive validity. Biodata analysis is nearly always very specific. Instruments are devised for, and scored in, organizations and they have to be regularly updated.

It has many obvious advantages. First, *objectivity:* The same questions are asked of everyone who completes the form, and the answers given are assessed in a consistent way. Second, *cost*: Although there may be fairly extensive R&D

costs, once criteria are known, biodata are very cheap. Biodata forms can be developed in multiple-choice formats, which are amenable to machine scoring or direct entry to a computer terminal. Third, *checkability*: It is possible, in theory at any rate, to check up on the answers of the respondents. This fact may reduce faking. Fourth, *validity*: Nearly all the studies have shown that biodata provides a valid and reliable way of selecting individuals. Questionnaires, are as good as ability tests. Fifth, *self-presentation*: Most people prefer, and expect, to be asked about their biographies rather than their personalities. For many, biodata is more preferable and acceptable than personality tests.

There are also well-known disadvantages to using this method. First, there is the issue of *homogeneity versus heterogeneity*: If many biographical items are used in selection, the organization inevitably becomes more homogeneous, which has both advantages and disadvantages. Heterogeneity may occur across divisions (with different criteria) but not within them. Second, there is the problem of *cloning the past*: Biodata work on the idea that past behavior predicts current performance, but if current criteria are very unstable (say in a rapidly changing market) one is perpetually out of date. Biodata may be best in stable organizations and environments. Third, there is the ever common problem of *faking*: Biodata has been shown to be fakeable. Checking that a person has not faked can be difficult and extremely expensive. Next, *fairness in the law*: If biodata items show major biographical correlates such as sex, race, religion, and age, one may want to select or reject particular individuals, which is illegal. Items such as age, sex, and marital status may in fact be challenged by the courts if such items are included in inventories for the purpose of personnel selection. The fifth issue is that possibly *minorities cannot easily be identified and treated fairly*: In setting up a biodata form, the link between the information on the form and suitability for the job needs to be established. This in itself tends to ensure that any other elements are excluded from the selection process. Biodata forms, especially when computer-scored, are completely blind to incidental items such as a person's name, which might indicate ethnic background.

Next, there is the critique that *biodata do not travel well*: The same criteria do not have the same predictability across jobs, organizations, countries, or time periods. Because criteria have to be established every time, the development of biodata can be expensive. Seventh, it should be recognized that this method is very *time consuming*: For example, it might take at least 12 months to obtain reliable, meaningful job-related data on new employees. If an organization does not have a regular intake of new staff, there could be 2 or 3 years delay between sending the draft biodata form to applicants and obtaining a sample of employees large enough to warrant further development work. Last, there is the issue of *shrinkage over time*. Biodata scoring keys do not appear to hold up indefinitely. There is evidence that the validity of biodata shrinks over time, and periodic revalidation and reweighting may be necessary.

Biodata has never become very popular nor has it ever really disappeared. There are probably three reasons why it remains a relatively little used assessment method. It takes investment of time and expertise to devise a biodata measure. Candidates do not like biodata and may think it is unfair. Organizations worry about litigation. However it is used as part data collection for many Assessment Centers. And of course, simply employing application forms to decide who to, and who not to, interview is of course, represents a use of biodata.

Cognitive and Mental Ability Tests

This refers to achievement aptitude or mental ability tests. Many terms cover the same areas: ability achievement, cognitive ability, mental ability, and intelligence tests. These are distinct from social intelligence tests, creativity, or divergent thinking tests.

Academic research has shown that quite consistently, cognitive ability accurately predicts job performance across *all* jobs but particularly in *complex* jobs. Many believe that intelligence is the *single best* predictor of (senior, managerial) work performance. All recent research points to the predictive power of cognitive ability and hence the importance of using these tests in selection.

The publication of a recent highly controversial book on intelligence – *The Bell Curve* by Hernstein et al. – led over 50 of the world's experts on intelligence to write to the *Wall Street Journal* on 15 December 1994. Their summary is an excellent and clear statement on what psychologists think about intelligence. However they do also note five points of what they call practical importance. First, IQ is strongly related, probably more so than any other single measurable human trait, to many important educational, occupational, economic, and social outcomes. Its relation to the welfare and performance of individuals is very strong in some arenas in life (education, military training), moderate but robust in others (social competence), and modest but consistent in others (law-abidingness). Whatever IQ tests measure, it is of great practical importance.

Second, a high IQ is an advantage in life because virtually all activities require some reasoning and decision-making. Conversely, a low IQ is often a disadvantage, especially in disorganized environments. However, a high IQ no more guarantees success than a low IQ guarantees failure yet the odds for success in our society greatly favor individuals with higher IQs. Third, the practical advantages of having a higher IQ increase as life settings become more complex (novel, ambiguous, changing, unpredictable, or multifaceted). For example, a high IQ is generally necessary to perform well in highly complex professional jobs; it is a considerable advantage in moderately complex jobs (crafts, clerical, and police work); but it provides less advantage in settings that require only routine decision-making or simple problem solving (unskilled work).

Fourth, differences in intelligence are certainly not the only factor affecting performance in education, training, and highly complex jobs, but intelligence is often the most important. When individuals have already been selected for high (or low) intelligence – and so do not differ much in IQ – as in graduate school (or special education), other influences on performance loom larger in comparison. Fifth, certain personality traits, special talents, aptitudes, physical capabilities, experience, and the like are important (sometimes essential) for successful performance in many jobs, but they have narrower (or unknown) applicability or 'transferability' across tasks and settings compared with general intelligence. Some scholars choose to refer to these other human traits as 'intelligences.'

The recent research evidence is very clear. The single best predictor of success in complex, changing managerial jobs is intelligence. Brighter people learn faster; they have a greater store of knowledge; and they tend to be intellectually more self-confident. They analyze problems more efficiently and are less threatened by change. One can, of course, be too bright for the job if it is unskilled or unchallenging. However, all mental ability tests are the focus of much controversy.

Mental ability tests predict work performance fairly well – as well as any other method available. The relationship between mental ability and work performance is continuous and linear – the brighter someone is, the more likely their work performance is to be good. Research on mental ability and team (rather than individual) performance suggests the existence of more complex relationships. Low scorers may hold the whole team back. Research on why mental ability tests predict work performance is less well developed, but suggests that mental ability leads to improved job knowledge, which in turn leads to better work performance. Mental ability tests create a large adverse impact on some ethnic minorities in the United States. There is a dearth of information on this issue elsewhere. Attempts to solve the adverse impact problem in the US include trying to identify features of mental ability testing that will reduce adverse impact. Attempts to deal with the adverse impact problem in the US include score banding, which defines a range of scores as equivalent, thus allowing selection within the band to be based on achieving diversity.

Personality Tests

The bottom line in this complex and very hotly debated area is this. The validity of personality tests in predicting future work performance depends on the test, the criteria, and the population sample. The tests are at their most useful/accurate when a good, well-validated test is used and the criteria are clear, well measured and theoretically related to the trait is measured.

As a result of some hundred years of research and disagreement researchers have (for the most part) agreed on what is the underlying structure (i.e., personality, periodic table) of traits. The Big Five factor model is widely accepted, but may not give the best prediction of work behavior, though other models exist. Recent studies have shown that two of these are relevant to all jobs, namely trait neuroticism and conscientiousness. Successful managers have a clear profile: they tend to be low on neuroticism (i.e., very stable), low on agreeableness, average on openness, high on extraversion, and very high on conscientiousness. Different jobs require different profiles but there are none where high neuroticism and low conscientiousness are an advantage.

Personality is a vaguer and more diffuse concept than ability, and there are many models of personality. Personality is most conveniently assessed by inventory or questionnaire. It can also be assessed by interview, Assessment Center, references, or peer ratings. Personality inventories are compiled using a variety of methods which generally overlap to some extent, including internal analysis by statistics, and external analysis comparing groups of people with known characteristics.

Personality inventories have limited value in predicting how well a person can do a job. Personality inventories may be more successful in predicting effort and drive. Personality inventories may also be more successful in predicting avoidance of deviant or problematic behavior at work. Personality inventories are self-reports and not tests, and can be faked. Faking appears to affect the outcome of selection. Personality tests are also widely used to screen out people with problem characteristics, such as violent tendencies, deviant sexual impulses, or dishonesty. Screening tests for employee honesty are surprisingly successful. Gender differences are often found with personality tests, but ethnicity differences do not seem to be a problem. Personality inventories have also been criticized on the grounds that some of their questions are unduly intrusive.

Among the main advantages of personality testing are first, that tests provide *numeric information*, which means individuals can more easily be compared on the same criteria. In interviews, different questions are asked of different candidates, and the answers are often forgotten or not properly analyzed. Next, tests give *explicit and specific results* on temperament and ability rather than the ambiguous coded platitudes that are often found in references. A percentage (provided of course that it is valid) makes for much clearer thinking about personal characteristics than terms such as 'satisfactory,' 'sufficient,' or 'highflier.' Third, it could be argued that tests are *fair* because they eliminate corruption, favoritism, old-boy, mason – or Oxbridge – networks from self-perpetuating. That is, if a person does not have the ability, or has a 'dangerous' profile, they will not be chosen, irrespective of their 'other assets.' Next, it is often asserted that tests are *comprehensive* in that they cover all the basic dimensions of personality and ability from which other behavior patterns derive. Finally psychometricians assert that tests are *scientific* in that they are empirically based on theoretical foundations; that is, they are reliable, valid, and able to discriminate the good from the mediocre and the average from the bad.

Many, often related, objections are made to psychological testing. Among the most common and sensible objections include the idea that many of these tests can be *faked*; that is, people like to put themselves in a good light and receive a good score so that they may be accepted, but this in a way reflects their real personality (some tests have lie scores to attempt to overcome this). Tests are unreliable in that all sorts of temporary factors, such as test anxiety, boredom, weariness, a headache, period pains, all lead people to give different answers on different occasions (although this is partly true, it is only a minor factor).

Most importantly, some people claim that most, if not all tests are *invalid*; they do not measure what they say they are measuring and those scores do not predict behavior over time. For many tests, this is indeed the Achilles heel and they are often lamentably short of robust proof of their validity. It has also been asserted that while tests might be able to measure all sorts of dimensions of behavior, but *not the crucial ones* to the organization such as trustworthiness and likelihood of absenteeism. Buying personality tests is like having a set menu, and what many managers want is an *a la carte* menu where they can select only factors or dimensions that they want.

People have to be *sufficiently literate* or articulate to do these tests, not to mention sufficiently familiar with North American jargon. Many organizations therefore believe their workforce

could not complete them properly, would take up too much time or would cause needless embarrassment. Others claim that there are not *good norms* (normative population data), at least for the population they want to test, and comparing them to White US students can be dangerously misleading. One old assertion is that *tests are unfair and biased* toward WASPS. Also, males tend to do better or get a more attractive profile and therefore get selected – which although ostensibly meritocratic, can conflict with antidiscriminatory legislation. It is also true that the *interpretation of the tests* takes skill, insight, and experience, and this is either too expensive or not available. In the wrong hands they are dangerous, because profiles are either given inaccurate or too literal interpretations. Finally *freedom of information legislation* may mean that candidates would be able to see, and hence, challenge either the scores themselves or their interpretation of the decisions made on them. The less objective recorded data the better. Finally, as tests become known, people could buy copies and practice, so that they know the correct or *most desirable answers*. This happens extensively with ability and personality testing and, when it does happen, results may have more to do with preparation and practice than actually *reflecting* true ability.

All assessment methods have advantages and disadvantages. Personality tests can greatly facilitate assessment. But the user needs to have some knowledge of test construction and theory both to choose tests wisely but how and when to implement them in the process. We do know that the two of the 'Big Five' factors seem to be important for all jobs – neuroticism which is a select-out factor because it is correlated negatively with success at work, and conscientiousness which is a select-in factor because it predicts work success. Test users would do wisely then to select tests which measure *both* these important traits.

But if tests do not predict behavior at work very well, the question is why not. First, there may be problems with the theoretical formulation in the first place, in that the personality theory or system has been poorly or inaccurately conceived. Quite simply, the theory upon which the test is based is wrong. Next, the measurement of the personality trait is poor for a variety of reasons, for example, it measures a single trait which is actually multidimensional. Also the measure has poor reliability and validity.

Abstract

Personality theories attempt to describe systematic differences between people in affect, cognition, and behavior, across situations and over time. Some theories attempt also to explain the causal roots of these individual differences, and biologically oriented ones focus on genetic and neurophysiological processes that underlie fundamental emotion and motivation processes. Approach-avoidance personality theories have dominated this literature: These are summarized along with the relevance of genetic and neuroimaging research methodologies. Conceptual issues in personality psychology are discussed to show how biologically oriented theories relate to other theoretical perspectives (e.g., social and psychometric).

Theories of personality aim to describe systematic differences between people in affect, cognition, and behavior, across situations and over time. A second major aim is to account for the causal roots of these individual differences, either in social, psychological, or neurological terms. Biological models of personality are specifically concerned with explaining the genetic and neurophysiological bases of these differences.

The phenomena of interest to the personality psychologist include both person and environmental factors, and their interactions. For this reason, there is a need to recognize multiple levels of analyses. Therefore, in a strict scientific sense, there cannot exist purely 'biological' or 'social' theories of personality. What 'prefix' theories of personality can claim to achieve is to emphasize the relative role played by a specific level of explanation. However, in order for any such theory to relate to personality factors (descriptions) and processes (causes), it cannot escape the fact that it is part of a broader conceptual framework. For example, the vast majority of personality theories start with a statistical description of systematic differences between people, typically relying upon psychometric principles and questionnaires (or some other form of self/other report). Data from these forms of measurement are neither purely 'biological' nor 'social' but entail 'method variance.' From a specific theoretical perspective, although such variance may be considered 'nuisance,' it is nonetheless real and reflects the multitude of influences on all forms of personality description. In addition, self/other ratings are about something (e.g., openness to experience of *what*?): From the respondent's point of view, test items are imbued with meaning. These observations do not undermine the attempt to construct a scientific theory of personality, but they do complicate matters and render single-level explanations problematic in terms of offering a comprehensive description and explanation of personality.

Once these complexities are recognized, it is possible to develop a 'social' theory of personality that emphasizes the relative effects of environmental factors, although such theories encounter significant problems in accounting for the full range of variation observed between people when tested in identical environments. In the case of a 'biological' theory of personality, it is simply not possible to ignore the role of the environment and broader social context: Biological effects are shaped by and expressed through the environment. In this strict sense, there cannot exist a purely 'biological' model of personality.

Far from being a counsel of despair, the above considerations highlight the important issues that need taking into account in understanding the biological approach to personality.

Surface Traits and Source Processes

In any personality theory, especially biological ones that lay stress upon underlying causal factors, there is an important distinction between two major levels of explanation: Surface traits and source processes.

In everyday life, it is typical to describe people's personalities in lexical terms. For example, we may describe John's characteristic ways of thinking, feeling, and behaving as 'smart,' 'fearful,' and 'cautious,' and these adjectives are readily understood and serve as a convenient means of communication, especially when they have an evaluative component (e.g., 'lazy,' 'ambitious,' 'aggressive'). We also talk about people's expected future behavior in the same manner; for example, John is 'trustworthy' and a 'regular' guy, and this allows us to predict the likely reaction of John to a range of situations.

Research personality psychologists have adopted essentially the same approach to describing personality, although their descriptions are couched in statistical terms. There is a long tradition of analyzing the ratings of a large number of trait adjectives to produce descriptive taxonomies, the most popular being the Big Five: Extraversion, Neuroticism, Conscientiousness, Agreeableness, and Openness to Experience/Intellect. Meta-analyses agree that these Big Five dimensions emerge from many existing personality questionnaires not designed specifically to measure them (e.g., Markon et al., 2005). These five dimensions describe systematic individual differences at the population level, and they are typically called 'traits' (or more generally, 'factors').

As a 'surface' level description of variation at the population level, the Big Five does a good (but not uncontested) job. But it should be obvious that statistical description at this high level of abstraction is bound to be influenced by a broad range of factors, ranging from biological (DNA) to societal. There are also likely to be significant cross-cultural differences in the formation and expression of these traits.

What the Big Five and other population-wide statistical descriptions of personality do not readily provide is information regarding the causal 'sources' of these surface traits: Scientific

explanation is about explaining, not just naming. What we observe at this surface level of description is the end product of a chain of interacting processes, and we can have little confidence in the assumption that these interactions are not complex. Since at least the time of Sir Francis Bacon, it is appreciated in science that it is difficult, sometimes seemingly impossible, to infer causes from observed effects. This is a major problem in personality psychology. To cut this Gordian knot, it is necessary to propose causal theories of underlying processes. Biological theories have been central in this scientific enterprise.

One important question that cries out for an answer is why do people feel, think, and act in the ways they do? One model is to assume that the environment (or situation) determines behavior, and that a history of reinforcement shapes individual propensities to respond to situations in specific ways. This behaviorist account has fallen out of favor for several reasons. First, it is tautological and circular in argument, and for a scientific theory it is remarkably immune to refutation. Second, there is now little doubt that the traits of personality are under heavy genetic influence (typically, heritability hovers somewhere between 40 and 60%). Third, even if the behaviorist account had merit, we would still have a legitimate right to want to know how observed effects are instantiated and processed by the brain. But these conclusions are not to discount the value of either a learning account or a reinforcement-based one. As shown below, both of these accounts have proved fruitful in the biological approach to personality.

Biosocial Perspective

If it is not possible to have a pure theory, what can be labeled 'biological' in personality psychology? For a start, such a theory would need to account for endocrine and physiological processes in explaining individual differences in response to the same environment. In this way, it lays emphasis upon internal agency, and not merely reactivity to external stimuli. We witness these features most clearly articulated in the first major biological approach to personality, namely H.J. Eysenck's arousal-activation (1967) theory.

The seeds of this major biological theory of personality were planted in Eysenck's 1944 seminal factor analysis of a medical checklist of 700 'war neurotics' invalidated out the British Army due to a failure of adaptation to the environment (in this case, military training during World War II). It will repay the student of personality psychology to consider the outlines of this theoretical approach as it reveals the assumptions of all biological theories of personality that took inspiration from it – and most did.

Eysenck's general approach was not so much 'biological' as 'biosocial.' It explicitly recognized that personality traits are the end product of the interaction of biological and social factors. In common with other biological theories of personality, Eysenck's theory points to the crucial role played by genetics and physiology, but he also pointed to the role of the *interplay* of genes/brain and the environment. Eysenck's starting point was to assume that human behavior and variations between people (i.e., 'personality') can be measured and classified in much the same manner as other biological phenomena – to him, there was nothing special about the 'mind,' no *élan vital*. His was a monist view of the mind/body (brain) problem.

A crucial assumption is that to the extent that environmental influences have lasting effects, they *must* go through the brain. By simple inference, individual differences in brain structure and functioning (heavily genetically influenced) affect the perception and analysis of the 'environment' and, thus, to a large extent, both define and determine its influence. For example, it is known that some people see events, as it were, through rose-tinted glasses, while for other people the hue of their glasses is blue. That is, given the same (objectively defined) event (the 'situation') there are different psychological consequences (e.g., emotional experience) depending on pre-existing dispositions (i.e., personality). At university, it is common for one student to perceive an examination as an opportunity to prove themselves, while for another student it is something to be dreaded – and these different psychological perspectives lead to different outcomes (emotional, cognitive, and behavioral, and in this example academic attainment). Contrary to purely social theories of personality, the environmental event (e.g., university examination) does not determine the psychological outcome; instead, biologically based individual differences in the construction and perception of the environment are the important ingredient. Today, this brain–environment interplay is a very fashionable topic of psychological research, seen in the guise of such effects as 'gene–environments interactions' (see below).

In Eysenck's personality theory, the conceptual bridge between the brain and the environment was conditioning (or more broadly speaking, learning). As there are significant individual differences in brain processes, so too there are differences between people in their rates of learning. This basic premise underlies many biological personality theories, which tend to focus on the role played by basic emotion and motivation systems, and how they lead to different forms of learning (i.e., modification of behavior by experience).

The biological approach also assumes that genetics provide a blueprint for the development of a specific phenotype (e.g., extraversion) but, critically, it is the interplay with environmental factors that determines what is observed – in much the same way that there must be a blueprint (or 'preparedness') for language acquisition but we all learn specific languages with local dialects.

Important questions are raised by this literature. How do biological processes affect perception and reactions to the environment? How do environmental factors affect biological processes? In other words, 'biological' and 'social' are bidirectional influences. Put another way, although nothing is more apparently 'biological' than DNA, this is merely a blueprint for potential development of the brain, which is proximally responsible for thoughts, feelings, and behavior. The brain is, indeed, a 'necessary' condition, but psychological phenotypes need 'sufficient' environmental conditions in order for them to develop and to be expressed.

A Functional Perspective

The search for the biological bases of personality traits must ask a number of questions, most important of which are What processes, and where to look for them? This problem is more real than apparent, and its resolution requires a conceptual

model of personality processes. The famous neuropsychologist Donald Hebb (1955) made the vital distinction between a 'conceptual nervous system' and the real 'central nervous system.' This distinction has proved important in suggesting how the scientific investigation of personality psychology might best proceed.

In order to understand why people react in different ways to the same stimulus or situation, we must first discover what drives people's actions and reactions. In the past, inferring motivation from observed behavior (and consistencies in behavior, 'personality') was something of a dark (and often murky) art. Psychoanalysis and a variety of 'projective' approaches may have enlivened psychology, but to many people they failed to throw proper scientific light on the true roots of motivation. Personality psychologists have looked elsewhere for inspiration.

One approach that has yielded theoretical fruit is based on the biology of motivational control systems. This approach operates on the premise that stable individual differences in behavior (personality traits) must be due to relatively stable individual differences in the operation of brain systems that produce (state) behavior from moment-to-moment. From this perspective, population-level traits reflect the operations of brain systems that have evolved to respond to different classes of functional requirements (Denissen and Penke, 2008). Accordingly, the search for biological underpinnings of personality should entail the search for answers to two questions: (1) What are the functions of specific reactions, and systems of reactions? and then (2) What is the neurophysiology of coordinated systems that mediate these reactions?

This functional approach has proved informative, and it has been augmented by two other approaches: The correlational approach (which biological processes are empirically associated with traits?); and the instantiation approach (what are the structures and workings of neurophysiological processes?). Most biological theories of personality combine different elements of these three approaches.

These approaches also help to differentiate the 'conceptual' (e.g., identifying the existence of causal systems by the construction of theories of behavior and learning) and 'real' (the 'wetware' of brain processes) nervous systems. In order to search for brain processes underlying the major systems of personality, it is necessary first to identify the existence of such systems by extracting separable factors of personality (traits) and building behavior-based accounts of such systems (e.g., classical and instrumental learning, and reward and punishment systems). One of the most comprehensive accounts of this whole literature is provided by Zuckerman (2005).

Functional accounts of personality have gained widespread popularity in recent years, and have afforded important insights in to human behavior. As discussed below, this approach provides a taxonomy of behaviors not in terms of the naming of traits and not even their specific behavioral outputs but, rather, in terms of the functions they serve. For example, different behavioral strategies (e.g., cooperation or coercion) may be identical in function (e.g., social influence) but their expression is influenced by context (e.g., power relationship). Contrariwise, the same behavior (e.g., cooperation) may serve different functions (e.g., altruism or submission), again depending on the context. Functions cannot simply be 'read-off' from behaviors; there is need for some form of conceptual nervous system to guide the search for the main systems of the real nervous system.

The functional perspective also throws light on the adaptive nature of, so-called, pathological behaviors and traits (e.g., anxiety and paranoia). The basic assumption is that personality traits – to the extent that they are systematic, genetically influenced, and pervade daily life – evolved by Darwinian natural selection, and thus have adaptive value – but this may not always be obvious. Adopting Darwin's hypothesis that psychological attributes are shaped by natural selection in much the same way as anatomical characteristics, modern personality theorists have come to favor accounts couched in terms of the functions of central states of emotion and motivation – an area of study suggested by Darwin himself in his work on the expressions of emotion in man and animals. These 'approach-avoidance theories' aim to describe the major systems that motivate behavior in reaction to classes of appetitive (rewarding) and aversive (punishing) stimuli, and to explain consistent patterns of individual differences in these behaviors. This literature is summarized by Corr (2013).

Approach-Avoidance Theories of Personality

Approach-avoidance theories of personality are based on the assumption that important classes of motivational stimuli can be grouped into 'rewards' and 'punishments.' Animals can be seen as cybernetic systems with attractors and repulsors (positive and negative goals) that have evolved to promote survival and reproduction. Without a tendency to approach beneficial stimuli (e.g., food, drink, and sexual mates) and to avoid aversive stimuli (e.g., predators and poisons) individuals and a whole species would simply not survive and pass on their DNA blueprint – the only thing that matters in biological inheritance.

Current approach-avoidance personality theories can trace their origins to early behavioral-learning researchers (e.g., Mowrer, 1960), who posited that two motivation/emotion processes underlie behavior: One related to reward (approach behavior and positive emotions), the other to punishment (avoidance behavior and negative emotions). This animal-based work migrated into personality psychology in the 1970s through the work of Jeffrey A. Gray (e.g., 1975), who argued that the major traits of personality reflect long-term stabilities in systems that mediate reactions to different classes of reinforcing stimuli, generating emotion and shaping ('motivating') approach and avoidance behavior. Neuroscience measures, including pharmacological manipulation, recording of neural activity, and neuroanatomical studies have been used to investigate the neuropsychological systems that underlie these reactions. A wealth of empirical research provides confirmation of the hypothesis that distinct and separable systems in the brain mediate reward and punishment-related emotion, motivation, and learning (Gray and McNaughton, 2000).

Personality Traits as Probabilistic Constants

To be of scientific value, a personality trait must be more than a score on a questionnaire: It must have predictive validity. In

biological theories, a personality trait is defined as a probabilistic constant in equations that predict the frequency and intensity with which individuals exhibit various motivational states, as well as the behavioral, emotional, and cognitive states that accompany these motivational states (Fleeson and Gallagher, 2009).

The biological approach aims to account for both the neuropsychological systems that are responsible for the states associated with any given trait and the parameters of those systems that cause them to differ across individuals. The systems themselves will be present in every intact human brain, but the values of their parameters will vary from person-to-person. Thus, for example, all people have brain systems that respond to punishments, but across individuals these systems respond differently to a given stimulus. It is the *typical* level of response of such a system in any given individual, averaged across different situations, that is associated with that individual's score on the personality trait in question. This is *not* to imply that an individual will respond the same way in all situations; rather, it implies that knowing the strength of the individual's trait predicts how he or she is likely to respond in a certain situation and, in particular, predicts variation in such responding across a set of individuals experiencing the same situation. This perspective means that the same person may respond quite differently in different situations (e.g., introverts under low and high level of arousal; Eysenck, 1967).

Many personality researchers have embraced this basic notion, and a number of personality models postulate traits reflecting sensitivity to reward and punishment (e.g., Elliot and Thrash, 2002). With the upsurge of neuroscience in psychology, there has been a marked increase of such theories, sometimes incorporated as part of larger theoretical schemes, associated with names such as Charles Carver, Robert Cloninger, Richard Davidson, and Jaak Panksepp. DeYoung and Gray (2009) summarize this large literature.

Reinforcement Sensitivity Theory of Personality

As Jeffrey Gray's early research was the principal impetus for reward/approach and punishment/avoidance concepts in mainstream personality psychology, and his work led to the formulation of the most elaborated biological theory of personality, it would be appropriate to use the current version of his theory, the reinforcement sensitivity theory (RST), to illustrate this broader scientific landscape.

Gray identified three primary systems that control reactions to punishment, reward, and conflict: The *fight-flight-freeze system* (FFFS), the *behavioral approach system* (BAS), and the *behavioral inhibition system* (BIS) (Gray, 1982; Gray and McNaughton, 2000; for summary, see McNaughton and Corr, 2008).

The one positive system, the BAS, is responsible for mediating reactions to all rewarding stimuli (which includes relief from nonpunishment) and it activates exploratory approach behavior. It is related to the emotion of hope and anticipatory pleasure and is measured by various personality scales, described below.

Turning to the defensive systems, the FFFS is responsible for mediating reactions to all punishing stimuli (which includes omission/termination of expected reward, and frustration), and is involved in active avoidance and escape behavior. It is related to the emotion of fear. In contrast, the BIS is activated by stimuli that indicate conflict between goals, especially between FFFS- and BAS-related ones. Upon activation, it inhibits the actions of the BAS and FFFS and generates cautious approach in potentially dangerous situations (i.e., passive avoidance). Also once activated, it generates risk assessment behavior, rumination, and increased arousal. Of interest, the BIS can be activated by the conflict of two opposing approach–approach goals, for example, receiving two equally appealing graduate school offers (the aversive component resides in the potential of making the wrong decision and incurring a relative loss). The BIS is related to the emotion of anxiety.

RST and Personality Traits

The most recent version of RST (Corr and McNaughton, 2008) proposes that the level of the trait Neuroticism reflects sensitivity to punishment and threat in general (both FFFS and BIS). However, within Neuroticism, there are two traits/emotions, each of which maps on to one of the two major systems for defensive behavior: *Fear* and *trait fearfulness* arise from the functioning of the FFFS; and *anxiety* and *anxiety-proneness* arises from variations in the sensitivity of the BIS.

Research evidence confirms that the personality traits associated with FFFS and BIS sensitivity are differentiable in measurement terms. Psychometric measures of fear and anxiety have been distinguished through confirmatory factor analysis (CFA), predictive validity studies, and associated facial expressions. Although Carver and White's (1994) widely used BIS scale was developed with only one avoidance system in mind, recent CFA studies show that this 'BIS' scale can be divided into separate FFFS (fear) and BIS (anxiety) components. There are now also studies using antianxiety and antipanic drugs to probe the FFFS and BIS, and these too support the separation of these systems. These studies are described by Corr et al. (2013)

Turning to BAS-related approach trait, Gray (1982) originally speculated that the trait associated with BAS sensitivity was 'impulsivity' largely because impulsive people are more likely to be sensitive to cues of the immediate possibility of reward. Although BAS sensitivity does play a role in impulsivity, researchers have since concluded that impulsivity is not its purest manifestation because it is determined not only by individual differences in the strength of impulses to pursue immediate reward but also by individual differences in the ability of top-down control systems to restrain and control those impulses (DeYoung, 2010). Indeed, Extraversion rather than impulsivity appears to represent the primary manifestation of BAS sensitivity in personality and various measures of reward sensitivity fall within the broad Extraversion factor (e.g., Gable et al., 2003).

Breaking down reward sensitivity into subfactors has not been as systematic as the approach to identifying traits associated with BIS and FFFS, largely because Gray elaborated only a single reward system. However, the most commonly used measure of BAS sensitivity has three subscales: Drive, Reward Responsivity, and Fun Seeking (Carver and White, 1994). Whereas Drive and Reward Responsivity both appear to characterize sensitivity to reward primarily, Fun Seeking appears to be equally related to impulsivity, and thus may not be as pure

an indicator of BAS sensitivity. How this biological model of personality is related to the population-level factors identified by the Big Five research tradition is summarized by Corr et al. (2013).

Genetics of Personality

One of the major correlational approaches to understanding the biology of personality factors and their underlying processes is genetics, which is seen in two forms: (1) Statistical/behavioral, and (2) molecular. This literature is reviewed by Munafo (2009).

Statistical/Behavioral Genetics

Using twin and adoption designs, this approach attempts to decompose the variance in some phenotype (e.g., Neuroticism) into genetic and nongenetic (i.e., 'environmental') components. By this means, heritability estimates are calculated. The literature shows that for almost all personality factors there is a substantial heritability (40–60%). Increasingly elaborate designs are being used to tease part genetic and environmental influences (e.g., new families after divorce which often have children with different biological fathers).

Molecular Genetics

In the case of molecular genetics, the approach is to find statistically significant associations between the frequencies of specific genetic variants (i.e., alleles) and scores on personality questionnaires. There are two main techniques used. The first is 'candidate gene' association technique, which first identifies specific genes thought to be important in the causal processes.

Candidate gene studies take as their starting point what is already known about the neurobiology of the trait of interest. This is used to identify genetic 'candidates,' in other words, genes that encode products involved in relevant neurotransmitter pathways. For example, when studying anxiety-related traits, such as neuroticism, genes involved in the serotonin pathway are the likely candidate, while for approach-related traits, such as extraversion or novelty seeking, genes involved in the dopamine pathway are the focus. As well as identifying a candidate gene in this way, it is necessary to identify a polymorphism within this gene (i.e., a region that can exist in multiple forms, 'alleles'). Genetic variation at this locus should, therefore, confer biological individual differences, which in turn should result in behavioral (phenotype) differences between people (e.g., anxiety).

The second approach is 'genome-wide association studies,' which takes a blind atheoretical approach and scans the entire genome for 'hot spots' of association – often revealed by Manhattan plots which highlight 'tall' associations. A very large number (500 000+) of genetic markers are examined to determine if any are related to the phenotype of interest and, if so, to what extent. Then, once the associated genetic markers are reliably identified, the process of exploration of the function of the related genes can start in earnest. Once again, the aim is to look for a significant correlation between genetic variation and phenotypic variation. To achieve reliable results, very large sample sizes are needed as the genetic associations are typically very small (usually less than 1% of phenotypic variance).

Although it is well-established that heritability for personality traits is substantial, the search for specific genes has not yet proved successful. This result may be due to several factors: The very small effect sizes of individual genes; the interaction of genes and the environment; and a basic lack of knowledge concerning how genes confer their effects on brain development and the expression of phenotypes. Certainly, the candidate gene literature is characterized by a pattern of early excitement followed by disappointment (Ebstein, 2006) as results have failed to replicate on independent samples.

Another reason for this lack of success may be the possibility of interactions between genes. This possibility is suggested by the work of Reuter et al. (2006) who found a significant DRD2 by COMT interactions (i.e., epistasis) for the Carver and White (1994) total BAS scale as well as for the subscales Drive (D) and Fun Seeking (FS). The details of this interaction are much less interesting than its existence: Genes may work together in influencing specific phenotypes.

Gene-by-Environment Interactions

There are now new approaches to exploring just how genes and the environment work together. This work throws new light on the role played by genes, but also what is meant by 'the environment.' To illustrate this approach, Poulin et al. (2012) found that genes act in tandem with a person's perceptions of the world (e.g., whether it is perceived to be threatening or not) to predict their level of generosity. Individuals who believe their surroundings are threatening are less likely to help others. However, this was found only in those individuals who lacked the gene variant that enable them to overcome their negative feelings. Specifically, genes related to oxytocin and vasopressin (hormones known to be related to maternal and prosocial behaviors) modify the effects of perceived threat (a measure of the environment) to predict engagement in volunteer work, charitable activities, and commitment to civic duty.

Neuroimaging and Personality

The biological approach to personality was given great momentum by the availability of functional neuroimaging (principally, magnetic resonance imaging, MRI), which permits direct investigation of the brain processes associated with an experimentally controlled performance task – this functional MRI is distinct from structural MRI, which is valuable in its own right (and comes as a 'freebie' with fMRI). It is now possible to relate personality traits to these brain processes. Although this literature is still in its infancy, it is already making progress in showing the brain instantiation of personality processes. This literature is summarized by Canli (2009).

Recent fMRI studies have demonstrated remarkably powerful and expected associations between personality traits, measured by a simple questionnaire, and brain activity during a number of cognitive and affective tasks (e.g., Mobbs et al., 2005).

Before the availability of functional brain imaging the only way to measure brain activity was with the use of electroencephalograms and event-related potentials – these remain valuable methods and are still used, especially because of their high temporal resolution (in milliseconds). The other main technique used by early researchers of personality and brain

function was lesions sustained through accidents or disease (or experimentally induced in laboratory animals, typically rats). These more traditional techniques still play a role, albeit a relatively declining one, in biological personality psychology.

As a specific example of utility of fMRI in relation to RST, Cunningham et al. (2010) provide evidence for different associations between FFFS- and BIS-related traits on amygdala activity (which is a brain region crucially involved in the detection of motivational salience). Their pattern of findings is consistent with the idea that the FFFS responds to all punishing stimuli, whereas the BIS responds to conflict associated with concurrent approach tendencies.

Conclusion

Biological theories of personality have made significant progress, in both theoretical elaboration of conceptual systems as well as uncovering the genetic and neurophysiological bases of systematic individual differences in thinking, feeling, and behaving. This research is embedded in a much broader conceptual framework of personality description and social-environmental influences. Gene-by-environment interaction studies are proving especially insightful, including showing how 'the environment' is, in many respects, a psychological construction of the brain and, itself, influenced by genetic factors.

Personality Changes During Adolescence Across Cultures

Abstract

The study of personality development in adolescence is a relatively new enterprise, with most of the research in this field having been conducted in the last 10 years. Reasons for the delayed interest in personality changes during adolescence are in the early views on personality development, the lack of a shared model and consensus on measuring stability versus change, and the focus of trait psychology on the adult personality. There are two broad views on the Big-Five personality development in adolescence: one which advocates adolescence as a key period of change, and another, which considers young adulthood to be more important. Regarding the changes in personality dimensions, research findings are mixed; but there are indications that after adolescence Extraversion decreases, Openness (Intellect) increases, while Agreeableness and Conscientiousness follow a curvilinear trend, decreasing in adolescence and increasing in early adulthood. The direction of change for Emotional Stability is still unclear. Personality traits in adolescence are related to important life outcomes; however, cross-cultural studies are still scarce.

Introduction

The study of personality changes in adolescence has only recently captured the interest of researchers, mostly over the past 10 years. There are several reasons for the scarcity of studies on personality development in general, and specifically during adolescence, prior to the last decade. The first reason was associated with the early views dominant in personality psychology which considered personality development to be mostly finalized by the ages of six or seven, i.e., in childhood. The second reason was the absence of a shared model in personality psychology, which hampered the whole field until the rise of the Big-Five model (Goldberg, 1990). The third reason was the lack of consensus regarding the measurement of personality development and methods for assessing change versus stability, not just during adolescence, but throughout the course of life. Finally, the fourth reason for the relative lack of studies on personality changes in adolescence was the focus on the adult personality in such studies, particularly those devoted to the structure of personality or the trait approach, which were conducted mostly on student samples.

Early Views on Personality Changes in Adolescence

Adolescence is often viewed as a period of 'storm and stress' (Arnett, 1999); it is therefore surprising that the studies on personality changes in adolescence emerged so late in the day. One of the reasons outlined above was associated with the view of the early personality theorists, especially Freud (1966), who claimed that the structure of personality with its main components of id, ego and superego, as well as the relations among those structures, are already determined by the start of the latency period, approximately at the age of six. Freud's views were shared by most of his fellow psychoanalysts, including Adler, Horney, Jung, and Anna Freud, who either emphasized the role of childhood as being crucial in personality development or just generally commented on the importance of other periods in life for personality change – as was, for example, Jung's insistence on middle age as a crucial period for full personality development.

The most elaborated view on personality development throughout the life cycle, within the field of psychoanalysis and probably the whole of personality psychology at that time, was delivered by Erik Erikson (1950) who posited the psychosocial theory of development. Erikson's theory was prominent for three major elements. The first was a detailed account of eight stages of development that spanned from birth till death, with each stage consisting of a basic crisis and the solution of that crisis (or lack thereof). The second was a notion that each crisis is salient during one stage, but has roots in a previous stage and consequences in the next stages. The notion highlights the continuity of personality development and could be translated to recent studies in the sense that each phase of personality change and stability is rooted in the previous stage, and reflects in the following stage. The third was an emphasis on adolescence as a key period in personality development with an emerging sense of identity. Postulation of Erikson's theory marked the end of the first era regarding views on personality development, where childhood was deemed the most important. It opened two doors for subsequent developments – the first being research on personality development throughout the whole life cycle and the other being the research on adolescence as a keystone for the formation of adult personality.

The Development of a Shared Model of Personality

The history of research on personality changes in adolescence was not only marred by the early disregard of other developmental periods besides childhood but also by the lack of a shared model which would organize and subsume the main findings. Personality psychology, probably partly due to developments in other disciplines in psychology and partly due to the complexity of its own subject matter, witnessed at least five major approaches, namely the psychoanalytical,

humanistic, social–cognitive, learning, and structural (dispositional), whose influences waxed and waned throughout the last century (cf Pervin et al., 2005). Each of these approaches had not just a unique view on what was most important for the study of personality, supplemented with specific research methods, but more importantly, a unique view on personality development. Even within the structural–dimensional approach to personality (frequently referred to as the 'trait approach'), the dominant model switched between Cattell's 16 factors and Eysenck's three dimensions, finally settling on the Big-Five (Goldberg, 1993) or the Five-Factor-Model (FFM) model (McCrae and Costa, 1997a). Personality traits reflect individual differences or dispositions in behaving, thinking, and feeling in consistent ways (Pervin et al., 2005). Since traits are both organizational constructs in the way they influence an individual in organizing his or her behavior, and developmental constructs in the sense that they show changes across the life course (Roberts et al., 2001), it is not surprising that the recent surge of interest in research for personality changes in adolescence, came after the consolidation of a shared model in the dispositional (or the trait) approach to personality.

The shared model of personality was built upon a lexical approach to personality with a simple premise that all significant individual differences can be found in language, since personality traits are central to human functioning and interactions. Working in the psycholexical tradition, Lewis Goldberg promoted at the beginning of 1990s the popularity of the Big-Five model with the main dimensions of Extraversion, Agreeableness, Conscientiousness, Emotional Stability, and Intellect. Costa & McCrae's FFM model, built upon the success of the lexical approach, differs from Goldberg's model only in the fifth dimension (Intellect), which in the FFM model is named 'Openness to Experience.' The first, broad, personality dimension of Extraversion pertains to traits of sociability, talkativeness, assertiveness, liveliness, impulse expression, boldness, and confidence. Most succinctly, Extraversion reflects an energetic approach of the individual to the social and material world (John and Srivastava, 1999). The dimension of Agreeableness refers to characteristics of understanding, warmth, compassion, trusting, helping others, peacefulness, and sincerity. Agreeableness is an interpersonal dimension mostly related to prosocial behavior (Graziano and Eisenberg, 1997). The Conscientiousness dimension comprises traits such as organization, work, responsibility, orderliness, efficiency, reliability, and impulse control. Since Conscientiousness refers to conformity and socially prescribed impulse control (Hogan and Ones, 1997), older models of personality used names such as 'character' or 'superego' to describe the core content of this dimension. Emotional Stability pertains to aspects of stability, even temper, calmness, happiness, tranquility, moderation, and unemotionality. Traditionally, personality psychologists were interested in the negative pole of this dimension, 'Neuroticism,' characterized by anxiety, depression, impulsiveness, vulnerability, and generally poor ability to cope with stress (cf Pervin et al., 2005). The fifth Big-Five dimension of Intellect refers to cleverness, ingenuity, imagination, depth, creativity, and reflection – thus concentrating on core aspects of being smart, whereas Costa & McCrae's fifth dimension of 'Openness to Experience' differs in content and apart from intellectual curiosity and imagination includes fantasy, aesthetics, feelings, ideas, actions, and values (McCrae and Costa, 1997b). Although the validity of the Big-Five model was confirmed in many languages other than English, the replication of the model was not universal, with studies yielding different numbers of factors; recent cross-cultural comparisons showed three factors (Extraversion, Agreeableness, and Conscientiousness) to be most salient and comparable in different cultures (De Raad et al., 2010). Nevertheless, the personality model with five factors became dominant in the discipline and spurred the research on personality development in subsequent years.

Measurement of Personality, Change, and Stability

After a consensus regarding the model on which to base the research was reached, the scientific study of personality changes still had to resolve one essential element: i.e., the issue of measurement. The choice of a measurement strategy can fundamentally affect the conclusions of a study on personality development. For instance, following the seminal publication of Costa and McCrae (1994), a common belief was that by the age of 30, personality would become 'set like plaster' and therefore, no personality change was expected after a person had entered the adult age. However, Costa and McCrae's main conclusions were based on rank-order consistency of personality or the relative position of an individual in a group through time. When researchers started to base their conclusions on mean-level consistency, i.e., on increases or decreases in personality dimensions over time, it became evident that there can be changes in personality even after the age of 30 years, especially reflected in increases in Conscientiousness and Agreeableness (Srivastava et al., 2003).

In trying to tackle the problem of stability versus change, the research on personality traits agreed that change is a multifaceted construct (Caspi and Roberts, 1999), and that conclusions regarding personality change in any given age could be faulty or even misleading if all (or at least the most important) facets of change are not addressed. Publications that followed (De Fruyt et al., 2006; Roberts and DelVecchio, 2000) identified five types of personality continuity, especially important in childhood and adolescence: the differential, mean-level, structural, individual-level, and ipsative. Differential and mean-level stability have been studied the most, the former describing the degree of stability of relative differences among individuals through time, and the latter describing the change of personality scores across time. Differential stability requires longitudinal studies and compares trait correlations over time; whereas mean-level stability can be measured in longitudinal studies but also in cross-sectional studies comparing age cohorts (De Fruyt et al., 2006). Meta-analyses are also valuable for both differential stability and mean-level stability studies (Roberts and DelVecchio, 2000; Roberts et al., 2006). The other three types of stability have been studied far less frequently. Structural stability seeks for invariance of covariance structures across time and is a prerequisite for mean-level stability studies since the conclusions about mean-level changes cannot be valid if the covariance structure changes over time (De Fruyt

et al., 2006). Individual-level stability pertains to a degree of change of a certain trait in a certain individual across time. Finally, ipsative stability examines the relative salience of attributes within an individual over time (Roberts and DelVecchio, 2000). The latter two stabilities are related to individual-level information and importantly complement the former two stabilities related to the group-level data.

Having fulfilled the final criterion necessary to reliably address the issue of personality change through the life course, (i.e., the comprehensive view on change vs. stability), the trait approach, over the past several years, witnessed a rising number of studies devoted to personality development, especially in childhood and adolescence.

Personality Changes and Stability in Adolescence

The Big-Five Dimensions and Lower-Level Constructs

Broadly speaking, there are two views on Big-Five personality development in adolescence. The first view considers that important changes in Big-Five dimensions occur during the period of adolescence (e.g., Branje et al., 2007; Soto et al., 2011), while the other view believes that adolescence is simply a preparation phase that lays the groundwork for change, and that most of the changes actually happen during young adulthood (e.g., De Fruyt et al., 2006; Roberts et al., 2006). Moreover, important studies with intermediate results (e.g., Allik et al., 2004), added to the cacophony of findings on personality change in adolescence.

Drawing on data from 92 studies, 113 samples and over 50 000 participants, Roberts et al. (2006) undertook a large meta-analysis and concluded that most of the changes in personality traits do not occur during adolescence, but rather during young adulthood, specifically from ages 20 to 40 years. Moreover, they concluded that adolescence was not a critical period for shaping personality traits, but a period of lull for trait development. Roberts et al. (2006) also argue that maturation is the major process behind changes in personality, reflected in the fact that most of the change occurs in young adulthood when people face major life transitions. However, Roberts et al. (2006), noted one important change in personality traits that does occur during adolescence, namely they reported a mean-level change in social dominance (a facet of Extraversion) that increased significantly in adolescence.

The study of De Fruyt et al. (2006) stands out as a rare example, as it examined all the five types of personality continuity described above in a single study. Working with a representative population sample and a twin and sibling sample of children and adolescents, the authors found evidence for structural stability at the level of five personality factors, stable differential or rank ordering of individuals in that period; and also reported that at the individual level, changes can be observed more frequently in young adulthood rather than in adolescence (De Fruyt et al., 2006). Regarding mean-level changes, De Fruyt et al. (2006) found some small-magnitude differences at the facet level in late adolescence and generally concluded that the level of personality continuity in adolescence is higher than usually expected.

The research of Allik et al. (2004), working with a large sample of 2650 Estonian adolescents found evidence at the mean-level score, for discontinuity of two Big-Five factors in adolescence, namely, Agreeableness and Conscientiousness and interpreted it as a developmental gap. In their study, Neuroticism and Extraversion smoothly transitioned from adolescence to young adulthood, while Openness tended to slightly increase during late adolescence. However, Allik et al. (2004) concluded, that when compared to the great changes in intellectual capabilities in adolescence, the development in personality traits was very small. Notable from this study is also the conclusion that a person is never more extraverted than at the age of 16 years, and that self-reported personality structure at the age of 16 years is the same as adult structure.

The study of Branje et al. (2007) is particularly interesting for findings on different mean-level changes in adolescence, depending on gender. While adolescent girls increased in self- and other-reported Conscientiousness, other-reported Agreeableness and Extraversion, and also self-reported Openness, adolescent boys decreased in self- and other-reported Extraversion and in other-reported Openness (Branje et al., 2007). The authors made a bold claim that in early adolescence, cerebral cortical development is faster in girls, and that this is parallel to earlier personality development. Branje et al. (2007) also concluded that there is evidence of increasing maturity even in adolescence, since adolescents participate increasingly in roles outside their homes and immediate family.

Finally, a recent study by Soto et al. (2011) indicated that regarding mean-level differences in Big-Five factors, unlike the conclusions outlined above, late childhood and adolescence are key periods for understanding personality differences throughout the life cycle. Working with a massive cross-sectional sample of over a million and a quarter participants from the world wide web, ranging in age from 10 to 65 years, Soto et al. (2011) concluded that some traits substantially differed only in late childhood, and some showed curvilinear trends, decreasing from late childhood to early adolescence and then rising as persons enter young adulthood. Soto et al. (2011) interpret these findings by paralleling the negative personality trends in adolescence with biological and social challenges of the same age. The strength of the study by Soto et al. (2011), apart from the large sample, is the fact that although they worked within the confines of a cross-sectional study, the authors managed to escape the pitfalls of cohort effects inevitably associated with such studies, by collecting data over a 7 year period, ensuring generalizability over cohorts.

Although the above section indicates that among researchers there still is no consensus as to whether adolescence is the key period for personality change, or whether young adulthood has taken over the role of being a cornerstone for personality maturation, some conclusions regarding the Big-Five dimensions and lower-level constructs in adolescence can be made.

Extraversion

Each of the Big-Five domains represents a broad construct at the top-level of abstraction in the personality hierarchy, and

consists of several lower-level specific traits. McCrae and Costa (1997a) posit that each FFM dimension comprises exactly six facets. The work on the Big-Five, on the other hand, was not univocal about the subdomains, with the number of facets ranging from only a few and up to nine per dimension, and finally settled on a two-level hierarchy with two broader aspects and 15 narrower facets for each of the Big-Five factors (DeYoung et al., 2007).

Just as there are different views on the change versus stability of Big-Five factors in adolescence in general, the research findings regarding the changes in the broad domain of Extraversion are mixed. Some deem that Extraversion shows mostly stability during adolescence and that there are no consistent changes at the level of the broad factor and associated facets (Asendorpf and Van Aken, 2003; McCrae et al., 2002). However, the study of Akse et al. (2007) found that the mean-level of Extraversion decreased from early to middle adolescence while the rank-order stability of Extraversion increased at the same age. Soto et al. (2011) found that overall, Extraversion showed a modest negative trend from late childhood to adolescence and then flattened through early adulthood. We can, therefore, conclude that if there is a change in Extraversion during adolescence, it will manifest in a decrease, at least after the age of 16 years (Allik et al., 2004).

However, all the Extraversion facets do not follow this general trend since Roberts et al. (2006) found that people increase in social vitality (marked by gregariousness, positive affect, and level of energy) in adolescence. Roberts et al. (2006) also reported an increase in the second facet of Extraversion, social dominance (marked by self-confidence and assertiveness) during the same age, although moderated by cohorts – with younger cohorts (born after 1940) showing a greater increase in the measured facet. Soto et al. (2011) found that the facet of activity showed a marked negative trend from late childhood to adolescence, while the facet of assertiveness showed only a modest negative trend in the same period.

Agreeableness

The findings on changes in the broad factor of Agreeableness in adolescence almost parallel the previous dimension (i.e., Extraversion) with mixed results. While a group of researchers found that there were no changes either at the factor or the facet level (McCrae et al., 2002), and that Agreeableness showed stability in adolescence (Asendorpf and Van Aken, 2003; Roberts et al., 2006), Allik et al. (2004) found that the level of Agreeableness decreased from 12 to 18 years. Soto et al. (2011) found a negative trend for Agreeableness from late childhood to early adolescence and then a positive trend from adolescence to young adulthood. To add to the variety of results, Akse et al. (2007) reported that Agreeableness increased from early to middle adolescence. We can summarize that if there is a change in Agreeableness in adolescence, it will follow a curvilinear trend. However, more research is needed to establish firmer conclusions.

Regarding the facets constituting Agreeableness, Soto et al. (2011) reported that altruism and compliance followed the same trends as broad Agreeableness, which would be a negative trend from late childhood to early adolescence and then a positive trend. The exception is compliance in boys which did not show a negative trend, since boys were low in compliance even at the age of 10 years.

Conscientiousness

Research on the development of Conscientiousness in adolescence again shows inconsistencies, with a group of researchers indicating no substantial change (McCrae et al., 2002; Roberts et al., 2006), and another group presenting evidence for change. De Fruyt et al. (2006) found evidence for a small decrease in Conscientiousness in the age group from 12 to 13 years. Similarly, Allik et al. (2004) found a slight decline of Conscientiousness from ages 12 to 18 years, from which there was a considerable increase. Soto et al. (2011) came to the same conclusions for Conscientiousness as for Agreeableness; both showed a negative trend from late childhood to early adolescence and then a positive trend to young adulthood. As outlined earlier, Branje et al. (2007) found an increase of Conscientiousness in adolescent girls, but no change in adolescent boys. Therefore, as with Agreeableness, we can conclude that if there is a change in Conscientiousness during adolescence, it will follow a curvilinear, nonmonotonic age trend. Still, more research on this topic is needed.

Regarding the facets, the study of Soto et al. (2011) showed that both self-discipline and order followed the same trends in adolescence as overall Conscientiousness, first expressing a negative trend from late childhood to adolescence and then a positive trend into young adulthood.

Developmental gaps for both Agreeableness and Conscientiousness in adolescence can be interpreted with a leap in socialization at the age of graduation from high school (Allik et al., 2004; McCrae et al., 2002).

Emotional Stability (Neuroticism)

Unlike the three previously described Big-Five factors, there is almost an universal consensus that Emotional Stability does change in adolescence. However, McCrae et al. (2002) interpreted the changes as modest, and noticed that girls increased in Neuroticism from age 12 to 18 years. McCrae et al. (2002) offered both a biological explanation for this effect (in girls' hormonal changes) and a cultural explanation (in society-imposed sex roles). However, Roberts et al. (2006) found the opposite effect: a small increase in Emotional Stability during teenage years, with no gender effects. A similar effect was found by De Fruyt et al. (2006): small mean-level decrease in emotional instability for age groups 10–11 years and 12–13 years. Allik et al. (2004) reported that Neuroticism showed a smooth transition from adolescence to young adulthood, meaning that the mean-level of adolescents resembles the mean-level of adults. Soto et al. (2011) found very different age trends for Neuroticism depending on gender. For females, Neuroticism showed positive trends from childhood to adolescence; while for men Soto et al. (2011) reported the opposite effect, a negative trend from late childhood. We can conclude that there are indications for changes in Emotional Stability (Neuroticism) during adolescence, but for final conclusions on the direction of change and gender differences, more research is needed.

Regarding the facets, Soto et al. (2011) found similar trends to those of overall Neuroticism: females showed positive trends

for anxiety in adolescence, while the opposite was found for men. Depression showed two peaks for females in adolescence and early adulthood, while for men there was a positive trend from late childhood into early adulthood.

Intellect (Openness to Experience)

The final dimension of the Big-Five or FFM should change in adolescence, judging by the available studies. Even McCrae et al. (2002), the main advocates noting no substantial changes in other dimensions during adolescence, report an increase in Openness for both genders and interpret such growth as being parallel with the growth of cognitive capacities and interest in various aspects of experience. The increase in Openness during adolescence was also supported by studies of Akse et al. (2007), Allik et al. (2004), Branje et al. (2007), and Roberts et al. (2006) who also reported a small increase in Openness in adolescence. However, the study of De Fruyt et al. (2006) found a negative trend for Openness in early adolescence while Soto et al. (2011) found negative trends from late childhood into early adolescence and further negative trends across adolescence for females. After that, there were positive trends for both genders into early adulthood (Soto et al., 2011). Therefore, we can conclude that the results indicating a positive change in Openness during adolescence prevail, however with contrary findings; the claim by Soto et al. (2011), of a curvilinear trend from childhood to young adulthood with negative trends at younger ages, deserves further investigation.

Regarding the facets of Openness, McCrae et al. (2002) found evidence for increase in four facets in adolescence: aesthetics, feelings, ideas, and values. However, De Fruyt et al. (2006) found a slight decrease for curiosity and creativity in the age group 12–13 years. Soto et al. (2011) found a negative trend from childhood to early adolescence for openness to ideas, and a positive trend for male openness to aesthetics from late childhood to young adulthood versus a flat trend for females.

Correlates of Personality Traits in Adolescence

Research on personality changes in adolescence is not only important per se, but also because there are findings linking the adolescent personality to important life outcomes. An early study of John et al. (1994) found that adolescent boys with externalizing behavior problems such as aggression, stealing, inattention, and hyperactivity had the pattern of low Agreeableness and Conscientiousness but also high Extraversion. Boys with internalizing behavior problems such as anxiety, somatic complaints, and social withdrawal were more neurotic and less conscientious, while delinquent boys were low on Agreeableness and Conscientiousness (John et al., 1994).

Shiner (2000) summarized the findings on childhood personality traits as important predictors of adaptation in adolescence: Extraversion was a predictor of academic achievement in children of school-going age but introversion was a predictor of achievement in late adolescence. 'Surgent engagement' (related to Extraversion) predicted late adolescent academic achievement negatively, while children high on 'mastery motivation' (related to Conscientiousness) showed less antisocial behavior and better social competence during adolescence. Moreover, children high on Agreeableness were more socially competent in late adolescence with less agreeable adolescents reporting higher levels of everyday conflicts and destructive conflict tactics; Academic Conscientiousness became more relevant for scholastic achievement over time, etc. (Shiner, 2000). The study of McCullough et al. (2003) showed that adolescent Conscientiousness was related to higher religiousness in early adulthood while the most emotionally stable adolescents showed the weakest relation between their religious upbringing and subsequent adult religiousness. The findings of both studies corroborate the notion of continuity of personality development, where childhood personality predicted the outcomes in adolescence; and adolescent personality was related to adult outcomes.

Cross-Cultural Variations in Personality during Adolescence

If the study of personality changes and stability in adolescence is itself in its adolescence, with most of the research having been conducted over the last 15 years, then the research on cross-cultural similarities and differences of personality in adolescence is in its true infancy. Most of the studies conducted so far used samples of participants either from the United States, from English-speaking countries or from the western world. The studies on adolescent personality outside of the westernized world are even more scarce than cross-cultural studies on adult personality, where the most research so far has been done on personality structure and assessment (Church and Lonner, 1998). McCrae et al. (2002) compared American and Belgian adolescents and found more evidence for similarity than for differences, concluding that there are indications for generalizability of developmental patterns. McCrae et al. (2000) compared British, German, Spanish, Czech, and Turkish adolescents with their adult counterparts and found that adolescents were lower then adults on Conscientiousness, again indicating generalizability. The study of Knyazev et al. (2008) generally found evidence for the five factor structure in children and adolescents both in Russia and Slovenia. Regarding mean-level differences, Slovenian adolescents scored higher on Extraversion and Openness, somewhat higher on Conscientiousness and Neuroticism, while Russians scored higher on Agreeableness, with economic, social, and climate factors as potential explanations for the differences (Knyazev et al., 2008).

However, most of the cross-cultural studies on adolescent personality, if not all of them, were made within the confines of etic strategy (Berry, 1969), where existing personality measures are imported, translated, and adapted to a different culture, and true emic strategies (Berry, 1969) are still missing in the study of adolescent personality. The universality and sufficiency of the Big-Five or FFM models in Asian contexts has been questioned and the etic approach was frequently criticized by Fanny M. Cheung and her coworkers (e.g., Cheung, 2004; Cheung et al., 2001, 2003). Specifically, Cheung and her colleagues came to the conclusion that 'openness to experience'

seems like an imported construct to Chinese culture and they discovered an indigenous dimension of 'interpersonal relatedness,' beyond the Big-Five, emphasizing interdependence in collectivistic cultures, such as in China (Cheung et al., 2001, 2011). Moreover, Cheung et al. (2011) pleaded for a combined etic–emic approach in personality psychology. Those studies, trying to identify indigenous personality constructs for any given culture and comparing them to other cultures are starting to appear within the lexical approach to personality (De Raad et al., 2010). These are conducted using adult samples, but would be useful to translate into research on adolescent personality as well.

Future Directions

The overview of research on personality changes in adolescence outlined above, shows that this is a new, vibrant, and promising field that can enhance our understanding of personality development and maturation, as well as underscore the importance of each developmental period, the important outcomes, and personality continuity through the life cycle. Although numerous important findings have stemmed from just a decade of research, many questions still remain to be answered. As noted here, rare are the studies that investigate all types of personality continuity and change (e.g., De Fruyt et al., 2006). Two types of continuity, differential and mean-level continuity, are still being studied the most. There are important findings at the level of broad Big-Five factors; however, the research on facets is still far from being conclusive, partly due to different conceptions of what lies below the broad factors. Integrative longitudinal studies on personality in adolescence and the whole course of life, should be conducted far more often in concert with other important measures of development, such as cognitive reasoning and moral judgment.

Finally, the lack of studies on personality changes in adolescence in cultures other than western societies is almost an embarrassment for the field, and future research should take a giant step toward that direction.

Abstract

Cognitive models of personality assume that people differ in their styles of understanding the world and themselves. More specifically, people differ in core self-beliefs and in the processes that shape and maintain the self. Contemporary research has focused on stable individual differences in cognitive content and process that may be associated with major personality traits. Studies of self-regulation and coping link traits to cognitive theories of these constructs. Studies using objective performance metrics allow traits to be further related to individual differences in information-processing. Cognitive neuroscience and cognitive-adaptive theory provide contrasting perspectives on the place of processing differences in personality.

Historical Overview

Cognitive psychology sees the person as an active information-processor. People are motivated to construct internal models of the physical and social world around them and their place in that world. These mental models both direct attention to personally relevant stimuli and guide response. People differ in the models they construct, and in the information-processing that supports model construction. The humanistic psychologist Abraham Maslow noted that if all you have is a hammer, everything looks like a nail. In relation to personality, people differ in the mental toolkit they possess for understanding the world. Some may define the world primarily in terms of its threats and dangers, so that their personalities are colored by strategies for identifying, forestalling, and coping with threat. Others may be more tuned into social affordances, so that the world is construed in relation to the social network around the individual.

The idea that personality reflects a style of personal understanding is simple and appealing, but growing in the shade of, first, psychoanalysis, and, subsequently, reductionistic neurobiology, it took some time for modern cognitive theories to develop. In the 1920s and 1930s, Gordon Allport defined traits as neuropsychic structures that render many stimuli functionally equivalent for the individual, e.g., in perceiving a multiplicity of stimuli as threats. The 'neuropsychic structure' was in part cognitive, in that it included general attitudes. Allport also recognized the metacognitive element of personality, in that individuals form beliefs about which of their traits are important to their sense of self and identity. Later theorists elaborated cognitive perspectives by emphasizing the roles of personal construction of the social world (George Kelly) and of representing events in relation to their importance to the self (Carl Rogers). Kelly's view of people as naïve scientists trying to understand their place in the world through reasoning and evaluation of events captures the spirit of theorizing in the 1950s, prior to the 'cognitive revolution' in experimental psychology.

Several developments of the 1960s helped to guide these early and somewhat prescientific insights toward modern cognitive theories of personality. First, Aaron Beck's schema theory of emotional disorder pinpointed faulty thinking and irrational self-beliefs as the basis for depression. It is a small further step to propose that normal variation in traits stems from milder biases in cognition. Second, social learning theorists, notably Albert Bandura, introduced cognitive constructs such as self-efficacy into traditional learning theory, suggesting paths for personality development in childhood. Third, the birth of modern cognitive psychology started to provide experimental paradigms that could be used to measure individual differences in information-processing, and so freeing personality research from the constraints of the armchair and the clinician's couch.

A fourth development was less obviously cognitive: Hans Eysenck's arousal theory of extraversion and neuroticism (Eysenck and Eysenck, 1985). Although skeptical of cognitive psychology, Eysenck's theory proved to be essential for later cognitive work. Eysenck's work established traits as 'real' personal qualities, expressed in individual differences in brain functioning. Researchers could now investigate cognitive bases for traits on a nomothetic basis (conforming to universal principles), without being confined to the idiographic qualities of the individual. Eysenck also emphasized the importance of experimental tests of predictions from theory. Relating traits to individual differences in arousability supported tests of how traits relate to perception, attention, memory, and response selection under different levels of environmental stress. Cognitive psychologists, of course, can infer relationships between traits and information-processing from such experimental paradigms. Most recently, the wheel has turned full circle in the form of cognitive neuroscience, which integrates classic psychobiological perspectives with information-processing theory.

The remainder of this article is structured as follows. The foundational place for trait theory in modern cognitive theory will be elaborated. Two variants of cognitive personality theory will then be differentiated. One is the cognitive self-theory built on the work of Rogers, Bandura, and, especially, Beck: the explanation of traits in terms of individual differences in core self-beliefs, and in the cognitive processes that shape and maintain those beliefs. The second looks more to experimental studies of information-processing and seeks to explain traits in relation to processing differences. The article will finish with perspectives from cognitive neuroscience and an adaptive account of personality.

Traits as Cognitive Constructs

Traits are stable personal qualities that moderate perception and action across a range of different situations (Matthews et al., 2009). They are often seen as basic temperamental characteristics, such as emotionality, that are rather closely tied to brain functions and influenced by heredity as well as environment. However, without denying the importance of neurobiology, the stability of traits may also be seen in cognitive terms. Bandura's developmental studies suggest that children internalize stable self-beliefs in long-term memory that influence emotional and behavioral response. In Beck's theory (Beck and Clark, 1988), an organized set of core self-beliefs is described as the self-schema. While the self is somewhat plastic in childhood, it becomes increasingly stable in the adult years (though not 'set in concrete'). Thus, extraversion may express a set of beliefs that one is socially dominant and that one is admired by others. Similarly, neuroticism may be associated with beliefs surrounding personal vulnerability. Further, traits can also be linked to action tendencies and response inclinations: beliefs about the value of social interaction in the case of extraversion, and about lack of effectiveness in coping in the case of neuroticism.

Contemporary research is often, though not exclusively, framed in terms of the five-factor model (FFM), which adds traits of conscientiousness, agreeableness, and openness to the Eysenck extraversion and neuroticism factors. The three additional factors may also be framed in cognitive terms. Conscientiousness is associated with persistence and effort in goal-directed behavior, as evidenced in numerous studies of academic and occupational achievement. A key cognitive factor associated with conscientiousness is self-efficacy, i.e., in believing that one can accomplish the tasks necessary to reach a goal, overcoming obstacles in the process. Conversely, the unconscientious student, lacking academic self-efficacy, may give up on assignments because of beliefs that the task is too hard. On the action side, conscientious individuals use task-focused coping strategies that promote systematic effort.

Agreeableness has been linked to social beliefs and behavioral inclinations. The more agreeable person is more likely to view other people as basically helpful and supportive, and to believe that cooperation is more successful than competition. Aggression is not identical to low agreeableness, but aligns with the lower pole of the FFM trait. Aggression may stem from distorted beliefs about others, such as falsely believing them to be hostile, and from tendencies to respond confrontively. The last factor in the FFM, openness, is typically defined in relation to interest in intellectual matters and activities, and belief in one's own intelligence. It may also encompass interests in the arts and in the unusual. Openness also correlates with cognitively defined traits, such as need for cognition, the tendency to engage in, and value effortful cognitive processing.

Thus, we could define each of the 'Big Five' (and other) traits in cognitive terms, as a set of characteristics beliefs about self and others, attitudes to key domains of life (e.g., work, socializing, study), and preferred options for taking action and coping with challenges and stressful events. Together, such characteristics define a self-schema that underpins the trait concerned. Evidence on relationships between the traits and relevant psychological constructs, such as appraisal, social attitudes, and coping, supports this conceptual picture. Nevertheless, three significant challenges to this viewpoint should be mentioned.

The first challenge comes from cognitive-social learning theorists such as Walter Mischel and Daniel Cervone (e.g., Caprara and Cervone, 2008), working in the tradition of Bandura. They question whether the beliefs that define personality are really general in nature, preferring instead to link beliefs to specific situations. A person might be socially self-confident on one setting but not in another, so that they would variously appear both extraverted and introverted, according to the environment. Situational influences on cognition are certainly important. The trait theorist would counter that people differ in general biases in thinking (e.g., in social self-efficacy), biases that may be differently expressed, or even reversed, across different contexts. As Allport (1931) stated, "Acts, and even habits, that are inconsistent with a trait are not proof of the non-existence of the trait." However, like Allport, social learning theorists are also prone to emphasize the idiographic beliefs of the individual over more general nomothetic principles.

The second challenge derives from neuroscience. Whereas a cognitive theorist might see the contents of the self-schema as a causal influence on personality, the neurobiologist see beliefs as an output of the brain system that is the true basis for the trait concerned. Thus, socially anxious people do not shun parties because they believe that others will mock them. An oversensitive brain punishment system simultaneously activates behavioral avoidance tendencies as well as thoughts of social threat. At the limit, the person's thoughts may be epiphenomenal froth with no causal influence on behavior. The issue here is the extent to which behavior is subject to neural reductionism.

The third challenge is accommodating emotion and motivation into trait theory. The recent popularity of 'emotional intelligence' is in part a reaction against seeing people as advanced biological robots for whom everything is merely an intellectual exercise, like the character of Spock in 'Star Trek.' Personality traits have defining emotional and motivational qualities that cannot necessarily be reduced to cognition. Notably, extraversion is often associated with positive emotion and approach motivations, and neuroticism with negative emotion and avoidance. Two resolutions are possible. On the one hand, it may be asserted that cognitive processes are indeed primary, but cognition should not be identified only with conscious, deliberate problem-solving; emotions are shaped in part by rapid, unconscious appraisal of stimulus meaning, for example. Alternatively, its cognitive accounts of personality are incomplete, with traits being higher-order qualities that bind together cognition, emotion, and motivation. There remain difficult and unresolved causal questions about how these distinct psychological domains influence one another.

Traits and Self-Beliefs

This section addresses further the role of the cognitive self in personality. At this point, it is important to distinguish content and process in cognitive theory. 'Content' refers to the nature of self-beliefs as they may be represented in long-term memory.

From a clinical perspective, abnormal personality would be a reflection of faulty data. 'Process' refers to the transformations of data that influence the contents of the self, and the behavioral control exerted by the self. In this case, abnormality is dependent on, as it were, faults in the mental subroutines for data processing.

Cognitive Content and the Self-Schema

Both content and process feature in Beck's schema theory (Beck and Clark, 1988). The content of thinking in clinical depression typically reflects a 'negative cognitive triad,' of a negative demeaning view of oneself, the world, and the future, e.g., "I am a worthless person, others despise me, and the future is hopeless." Beck also identified faulty processing that contributes to depression, such as overgeneralization, e.g., assuming one is universally denigrated because of a critical remark. Beck's later theory differentiated depression from anxiety primarily in terms of content (the content-specificity hypothesis). Whereas depression is characterized by themes of worthlessness, loss, and hopelessness, thoughts in anxiety revolve around beliefs that threats are imminent and the person is ill-equipped to deal with them. In fact, tests of the content-specificity hypothesis have had mixed outcomes, and there is some general negative self-referent content common to both emotional disorders.

Cognitive content may play a corresponding role in trait variation in normal populations free of clinical disorder, as shown in studies of neuroticism and trait anxiety. Dispositionally anxious individuals typically express a range of negative self-beliefs including overestimation of risks and underestimation of personal competence and success. Beliefs may be tied to a specific context; individuals high in test anxiety may believe they will fail at even mildly challenging tests, those high in computer anxiety believe they cannot cope with information technology, and so forth (Zeidner, 1998).

Judge et al. (2004) pointed out that, although neuroticism is typically defined as an emotional trait, it correlates substantially and negatively with three important cognitive constructs: self-esteem, locus of control, and generalized self-efficacy. Locus of control refers to the person's style of attribution toward important events. An internal locus signifies personal control of destiny, and is related to emotional stability. They showed that these three belief-based constructs could be subsumed together with neuroticism under a common factor of core self-evaluations. Whereas neuroticism is strongly negatively correlated with the factor, extraversion and conscientiousness are both associated with positive self-evaluations. Core self-evaluations predict job performance, via motivational variables such as goal setting and goal commitment.

Cognitive Process Factors

Process factors are important in part because of individual differences in self-regulation. This term refers to the management of thoughts, feelings, and actions as the person pursues personal goals. Self-regulation implies monitoring one's own internal states to assess the state of progress; indeed emotional responses may be tied to goal progress. It also implies development, application, and monitoring of strategies for maintaining progress. Such strategies may be directed toward regulating personal behavior and action, the external environment, and internal states, including emotion regulation. Similar cognitive models have been applied in other domains of psychology. Lazarus' (1999) transactional theory of stress and emotion describes a cycle of appraising environmental demands, initiating coping, and then responding to feedback as the interaction between person and environmental demands unfolds.

Personality traits correlate with the process variables described by theories of self-regulation and coping. Assuming a cycle of monitoring and 'action' (broadly defined), traits might influence both self-perceptions and choice of regulative or coping strategy. Studies reviewed by Robinson and Sedikides (2009) link traits to processes that shape and maintain the self, such as self-enhancement and self-verification (confirmation of strongly held views of the self). People may use the generalized self-knowledge associated with traits to 'fill in' appraisals of events when lacking detailed information. Thus, among individuals who have trouble making fine discriminations between stimuli, neuroticism is especially predictive of distress. Those high in neuroticism presumably draw upon their negative self-schema in evaluating incompletely encoded stimuli.

Many studies of traits and appraisals investigate both demanding real events, and controlled laboratory scenarios, such as failing on a performance task. Individuals high in neuroticism and trait anxiety tend to appraise events as being more threatening, and themselves as lacking self-efficacy and control over events. Because appraisals are a direct driver of emotional response (Lazarus, 1999), such findings help to explain why dispositionally neurotic individuals are prone to negative emotion. Traits for negative emotionality also tend to be associated with self-consciousness, elevating the salience and immediacy of negative feeling states, thoughts, and images. Conversely, the tendencies toward happiness and positive affect of extraverted individuals may reflect a bias toward appraising events as being challenging, i.e., offering benefits even if there are obstacles to be overcome.

Traits also predict coping preference. There are various classificatory schemes for coping, most simply Lazarus' (1999) distinction between problem-focused (externally directed, action-oriented) and emotion-focused coping (internally directed, regulation of feelings and thoughts). Neuroticism is associated with potentially maladaptive forms of emotion focus, such as self-criticism, and extraversion with more constructive, problem-focused strategies. Associations between these traits and coping style may also contribute to mediating their impacts on emotion. Conscientiousness is also associated with strategies oriented toward controlling the situation including problem focus and cognitive restructuring.

Another important type of process is metacognition. In monitoring their mental landscape, people make judgments about the importance and significance of their thoughts and feelings, which in turn may drive strategic efforts to regulate them. In emotional disorders, people are often disturbed by thoughts and images that seem to intrude automatically into consciousness. Such intrusions reflect cognitive contents as previously described, e.g., images of some feared disaster in

the case of anxiety. However, the impact of intrusions is accentuated by metacognitive processing (Wells, 2011). Patients with generalized anxiety disorder tend to worry about their own worries (metaworry), a tendency that prolongs worry and serves to maintain the disorder. Similarly, unproductive rumination is characteristic of depression, and both worry and rumination feature in subclinical neuroticism. A variety of metacognitive styles can be identified that are often maladaptive (Wells, 2011). More constructive forms of emotion regulation may involve reappraisal of the disturbing thought or image to understand its origins and lack of real significance.

Wells and Matthews (1994) developed a cognitive theory of normal and abnormal negative emotionality that pulls together several of the issues discussed above. The self-referent executive function (S-REF) theory describes a cognitive architecture with three levels. A level of self-knowledge defines the stable generic self-knowledge (content) that shapes processing of self-relevant information. Self-knowledge may be declarative (accessible to consciousness) or procedural (specifying a processing routine that may not be conscious). An executive system accesses self-knowledge in appraising personally relevant events, including internal 'events' such as intrusive thoughts, and in regulating coping. It also initiates metacognitive processing that may direct attention toward thoughts and images. Intrusions are generated by a third level of automatic processing networks that often operates unconsciously but may activate concepts and images to such an extent that they break through into awareness and initiate executive processing.

In 'normal' anxiety and dysphoria, negative self-knowledge may activate the executive with some frequency, but, typically, appraisal and coping are adequate to prevent major life disruption. In clinical patients, however, several factors may come together to maintain extended cycles of perseverative worry or rumination, including unrealistically negative appraisals, choice of ineffective emotion-focused coping strategies, and metacognitions that serve to lock attention onto the internal worry cycle. The person cannot effectively refocus attention on the external world, impairing effective coping. Furthermore, episodes of worry may strengthen the dysfunctional self-knowledge that contributes to the syndrome so that a vicious cycle develops. The S-REF model emphasizes that personality dysfunction is not just a matter of abnormality in content and/or process but an outcome of disordered dynamic interaction between person and environment.

Theories of personality and emotion based on cognitive theories of self-regulation or stress have several strengths. They provide integrated accounts of traits such as anxiety that accommodates evidence from a variety of sources, including evidence on clinical patients and normally functioning individuals. Evidence is supportive of a variety of specific associations between traits and cognitive constructs, such as appraisal, coping and emotion-regulation strategies, and metacognition. Theories are also capable of relating personality to the dynamic interactions between person and environment that feature in contemporary cognitive theory. That is, personality is more than a set of static descriptive characteristics. In clinical psychology, cognitive models provide the basis for an array of cognitive-behavioral therapies (Beck and Clark, 1988; Wells, 2011).

Limits of Cognitive Theory

However, there are also limitations to cognitive theory. Perhaps the most severe is that much of the evidence on which theory is based relies on self-reports of various kinds, including questionnaire measures of constructs such as coping, and patient reports of symptoms. Recent work on implicit aspects of personality shows that much 'cognitive' processing is unconscious and cannot be assessed validly using self-report. Reporting of explicit cognitive content and process may be possible, but also subject to bias, as a consequence of lack of personal insight and awareness, or of deliberate self-distortion (also a feature of self-regulation). Self-verification, for example, may lead to people exaggerating the extent to which they cope consistently with different types of stressor. It may be informative to look at how individuals cope with specific challenges rather than relying on general self-assessments of coping style.

Studies of implicit personality (Schnabel et al., 2008) show the importance of objective measures of cognition. One of the classic techniques is the implicit association test (IAT). Originally developed to assess unconscious social biases, such as prejudice, it has been adapted to assess personality. The test uses reaction time data to determine how easily the person associates various personality characteristics with the self. Implicit measures such as IAT may predict nonconscious behaviors better than explicit scales do. There are typically positive but modest correlations of around 0.3 between corresponding explicit and implicit measures. Thus, while questions remain about the reliability, stability, and validity of implicit trait measures, there appear to be cognitive aspects of personality that do not register on standard questionnaires.

Information-Processing Models for Personality

Evidence for implicit cognitive traits highlights the need to integrate theories of personality with cognitive psychological models that provide fine-grained accounts of information-processing based on objective data on speed and accuracy of performance. Two broad currents of research have been influential in this area. The first starts from the experimental studies of Eysenck (Eysenck and Eysenck, 1985), which showed that traits correlated with performance on tasks such as choice reaction time, vigilance, and short- and long-term recall from memory. In keeping with the stress research of his day, Eysenck attributed these associations to individual differences in arousal of the cortex. In the 1970s and 1980s, stress researchers rejected arousal theory as being overly simplistic, and unable to account for the variation of stressor effects with the cognitive demands of the task. Indeed, arousal did not seem, in general, to play the mediating role stated by Eysenck's personality theory (Matthews and Gilliland, 1999). Rather than investigating performance in some global sense, it is more informative to test how traits relate to different cognitive functions, and the specific processes that support these functions.

An influential cognitive theory was proposed by Humphreys and Revelle (1984) based on 'processing resources' as mediating constructs. In attentional theory, a resource is a general-purpose reservoir of 'mental energy' that facilitates certain processes (controlled processing). Humphreys and

Revelle (1984) differentiated a resource used for sustained information transfer (attention) from a resource for short-term memory. The resource concept is metaphorical, and open to criticism as lacking in precision, but it has proved useful in explaining and predicting how attention varies with task demands. Humphreys and Revelle also retained arousal as a mediating construct. Details of their theory are beyond the scope of this article, but their causal assumptions were that personality traits interact with environmental factors to influence arousal, which influences availability of the two resources, which in turn influences performance on sufficiently demanding tasks. They used the theory to explain why extraversion–introversion effects on intelligence test performance varied with arousing agents such as caffeine and time of day.

A second longstanding line of research originated with one of the first cognitive theories of trait expression, Charles Spielberger's (1979) theory of anxiety traits and states. Consistent with worry being the element of anxiety most harmful to attention and performance, Spielberger attributed anxiety effects to disruption of information-processing. More specifically, anxiety may be associated with diversion of the focus of attention from external to internal processing, with loss of attentional resources to processing personal concerns, or to loss of working memory space (Zeidner, 1998). The conclusion that anxiety disrupts attention is generally sound, but cognitive psychological research shows that 'attention' is not a unitary process. Prioritizing information, multitasking and sustaining attention over time all depend on multiple processes that may be differentially sensitive to personality.

The attentional control theory (ACT) of Eysenck and Derakshan (2011) focuses on the cognitive control or executive processes that afford voluntary control of attention. Various specific processes may be distinguished, including inhibition of task-irrelevant stimuli, switching between different task sets, and updating the contents of working memory. In general, anxiety effects on attentional tasks are somewhat inconsistent. Sometimes anxiety impairs performance, sometimes not. According to ACT, anxiety impairs inhibitory processes most strongly, so that anxiety is most damaging when the task requires the person to ignore distracting stimuli. Fine-grained information-processing accounts may help to explain the sometimes elusive effects of traits and emotional states on task performance.

Another important area of research concerns selective attention. In anxiety, and other emotional states, there appears to be a bias toward attending to congruent emotive stimuli (Cisler and Koster, 2010). That is, in anxiety, attention is drawn toward threats or sources of threat, even when the stimulus is irrelevant to the task. Bias is demonstrated with a version of the Stroop test, in which the person must name the ink colors of words that include threatening words such as murder and failure. Anxious individuals (patients and normal samples) are slow to name the colors of threat words, even though the task requires them to ignore word meaning. There appears to be a robust, moderate effect for threat-related attentional bias in anxiety, demonstrated using a variety of different experimental paradigms. The effect works for subliminal presentation of stimuli, where, on the Stroop test, for example, the person could not consciously identify the word stimulus. This finding suggests a bias in early encoding processes operating prior to conscious attention (although the bias may be modified by strategic factors). In ACT (Eysenck and Derakshan, 2011) threat-related bias is attributed not only to the attention-engaging effect of threat stimuli, but also to weak inhibitory control.

Studies show reliable associations between traits and information-processing, provided that care is taken with methods and tasks. However, questions remain about the broader significance of these findings. The major traits relate to a variety of individual differences in information-processing, which cannot be reduced to any single underlying mechanism (Matthews and Gilliland, 1999). The trait relates to a 'cognitive patterning' of typically modest processing biases (Matthews, 2008). It is debatable what such findings mean for the view of traits as coherent, unitary characteristics for which personality theory typically strives. This article finishes with two contrasting perspectives on the theoretical relevance of information-processing studies. First, from a 'bottom-up' perspective, variation in processing may be informative about individual differences in brain functioning that shape personality, as specified in contemporary cognitive neuroscience. Second, from a 'top-down' perspective, the performance data may be understood in the context of traits as adaptive factors.

Cognitive Neuroscience Perspectives

Traditionally, neurobiological theories of personality have referred to broad constructs such as arousal or sensitivity to reward and punishment. However, cognitive neuroscience suggests that a more fine-grained account of biological bases for personality may be attained. The neural networks that control attention are increasingly understood. For example, Michael Posner differentiated networks for executive control, spatial orienting, and alertness. Use of tasks informed by such theories affords inferences about individual differences in brain function, inferences that can be substantiated using methods including brain imaging. For example, one expression of the threat bias in anxiety is spatial orienting toward threat (see Cisler and Koster, 2010). Performance studies show that anxiety relates most reliably to one of the several attentional functions supported by the spatial orienting network: disengagement of attention from a location associated with threat. Brain-imaging studies localize the effect in the prefrontal cortex and functionally related structures. Other mechanisms contributing to observed affective biases can be triangulated similarly (Cisler and Koster, 2010). An additional step is to specify the dynamics of the neurocognitive architecture thus identified using connectionist models of processing.

Similarly, at least some extravert–introvert differences in performance may be attributed to dopaminergic functioning. Simplifying considerably, ascending dopaminergic afferents from the midbrain innervate a variety of structures including prefrontal areas that support executive control. Brain-imaging studies support the neurobiological hypothesis that extraversion is associated with greater activity in these pathways, in rewarding conditions (Kennis et al., 2013). To the extent that dopaminergic activity can be linked to functioning of the prefrontal cortex, we have explanations for extraversion effects on tasks dependent on this brain area, including working

memory and executive control tasks. It remains challenging, however, to show that observed performance effects are directly mediated by specific brain processes.

Thus, progress is being made in integrating neurobiological and cognitive psychological perspectives on personality traits. Nevertheless, there remains a concern that identifying traits with sets of discrete neurological biases may be missing the forest for the trees, especially in relation to explaining variation in the 'cognitive self' and the role of cognitive content. Neurobiological understanding of traits requires supplementation with psychological accounts that specify at a more abstract level how variation in self-content and process translates into different styles of self-regulation and adaptation to environmental challenges.

Cognitive-Adaptive Perspectives

Matthews (2008) has proposed a cognitive-adaptive theory of traits that poses the question of the functional significance of the cognitive correlates of traits. Extraverts tend to be superior in selective attention, verbal working memory, and speech fluency, but poorer than introverts at vigilance and reflective problem-solving. How does this package of cognitive characteristics influence extraverts' adaptation to social and physical environments? The answer may be that the cognitive patterning supports an adaptive specialization toward challenging social environments that extraverts are known to favor. However, the role of information-processing is indirect, in affecting the speed of acquisition of the contextualized skills needed for specific environments. The cognitive characteristics of extraversion facilitate the acquisition of conversational skills, for example, that allow the extravert to navigate through demanding scenarios such as high-stakes financial deal-making and standing out at a party. Conversely, the introvert, while vulnerable to social overload, has the advantage in contexts where social reinforcement is infrequent, such as working as a programmer.

A similar analysis can be applied to other traits. For example, level of neuroticism may represent the person's place on a spectrum of strategies for adapting to social threat, ranging from anticipation of threat and avoidance (high neuroticism) to stoic direct management (low neuroticism). As with extraversion–introversion, the characteristic strategies of those high and low in neuroticism may be effective in some social environments but not others. The cognitive-adaptive perspective allows cognitive correlates of traits to be understood in terms of underlying purpose, and so provides a means for integration findings on a wide range of trait attributes, at different levels of abstraction from the neural substrate.

Abstract

This article first defines and compares the concepts of temperament and personality. Second, it discusses contextual variations of temperament and personality, and the distinction between continuous and categorical views of these two concepts. Third, the article focuses on development of temperament and how temperament contributes to development of personality. Finally, the possible influence of culture on temperament and personality development is discussed.

The Concepts of Temperament and Personality

Temperament can be defined as enduring individual differences in reactivity and self-regulation that appear early in life and have a presumed biological basis. Reactivity refers to individuals' responsiveness to changes in their external and internal environment, and is manifested in latency, duration, intensity, and frequency of motor, affective, and attentional reactions (Rothbart and Bates, 2006). For instance, infants vary in their response to a new moving object; some infants become aroused easily and thrash or cry within a few seconds while others show limited arousal to the same stimulation (Kagan and Snidman, 2004).

Self-regulation refers to neural and behavioral processes that function to modulate reactivity and is apparent in individual differences in effortful control, or the capacity to focus and shift attention, to inhibit a dominant response and/or to activate a subdominant response, to plan, and to detect errors (Rothbart and Bates, 2006). Some children are better than others in sustaining their attention, delaying gratification, regulating their emotional arousal, and suppressing and initiating activity to signals or instructions.

While temperament is limited to basic processes of reactivity and self-regulation in affect, attention, and activity, personality refers to a broader range of enduring individual differences in thoughts, feelings, and behavior and includes goals, motives, identities, habits, coping styles, values, beliefs, and other processes that are not typically considered aspects of temperament (McAdams and Pals, 2006). For instance, individual difference in the view of the self in relation to others represents an aspect of personality but not temperament.

Despite of the distinctions between temperament and personality, there are also similarities between these two domains of individual differences (Caspi and Shiner, 2008). Both temperament and personality traits appear to be partially but not uniquely heritable, and are shaped by maturation and experience. Both are relatively stable within similar contexts but are less consistent in distinct situations. The core aspects of temperament and personality, particularly during childhood, are similar; both involve individual variations in effect and self-regulation.

It is helpful to consider early individual differences as temperament, which then sets constraints on the later development of personality. Children's maturation and experience permits the development and expression of new aspects of personality that are not captured by early differences in temperament.

Temperament and Personality in Context

Temperament and personality both describe individual differences that are not continually expressed but require eliciting conditions (Rothbart and Bates, 2006). Temperament and personality may be viewed consisting of a pattern of 'if-stimulus-then-response' dispositions that are not expected to show situational invariance (Caspi and Roberts, 2001), but rather to reflect what (Murray, 1938) referred to as 'environmental press'; where a particular trait is elicited in some contexts but not in others, and a particular context may evoke behavioral expression of some but not other traits. For instance, highly reactive children are typically distressed by novelty, discrepancy in stimulation, or cues for punishment, but they may be at ease when interacting with siblings or familiar peers. Moreover, a given context will differ in its effects on individuals who differ in temperament or personality. Thus, going to a new place may be exciting for sociable children who enjoy and seek stimulation, but may be unpleasant for shy children who are afraid of novelty.

Continuous and Categorical Views

There is disagreement as to whether temperament or personality should be viewed as a continuous dimension or as a qualitative category (Kagan and Snidman, 2004; Shiner et al., 2001). While there appears to be a preference for the continuous view of temperament, the emphasis on dimensions that are shared by all individuals, could mask configurations of multiple traits within a particular individual that may represent a qualitatively unique temperament or personality category. An integration of both continuous and categorical approaches of temperament has been useful. In their pioneering work, Thomas and Chess (1977) first identified nine primary dimensions that can be used to rank order temperament in all children. Based on the within-individual configurations of these nine dimensions, they later categorized children into three types: difficult, easy, and slow to warm up. Children who

were classified as difficult were more likely than those classified as easy and slow to warm up to develop behavioral and psychological problems.

Development of Temperament

An infant is not born with a full complement of temperamental characteristics; many aspects of temperament emerge later due to a complex interplay among heredity, maturation, and environmental influence. While individual differences in reactivity emerge as early as in the first year of life (Fox et al., 2005), temperamental self-regulation, particularly effortful control, does not emerge until toddlerhood, and continues to develop in preschool years (Rothbart, 1989). The late developing nature of effortful control and its possible role of regulating reactivity may partly explain why many young children who were initially identified as 'highly reactive,' i.e., being fearful and inhibited, became less so or even uninhibited years later (Fox et al., 2005).

The development of effortful control is susceptible to not only maturation, but also individual experiences. For example, the integration of threatening or challenging environmental information into a child's mental representations may facilitate the development of effortful control. With increasing effortful control, the child can develop goal-oriented coping strategies to modulate negative emotions, to anticipate novelty or punishment cues by recognizing contextual information, and to evaluate the potential consequences of their actions and voluntarily decrease attention to unpleasant stimuli while shifting attention to relieving information (Rothbart and Bates, 2006). In addition, socialization, particularly parents' child rearing practices, facilitates the development of children's cognitive representation of what constitutes normative social standards and how personal actions may affect others' psychological experiences. Thus, effortful control increasingly coordinates with internalized goals, and operates to regulate a child's performance in a means–end fashion that is consistent with societal norms.

Given the evolving interaction among heredity, maturation, and environmental influences, temperament changes across age. Temperament during infancy appears to include three broad dimensions: two dimensions of reactivity, surgency/extraversion, and negative affectivity, and the third dimension of orienting/regulation. Surgency/extraversion is defined by approach tendency, activity level, simulation seeking, positive affect, and high intensity pleasure, whereas negative affectivity refers to negative emotions such as sadness, frustration, and fear. Orienting/regulation comprises of low intensity pleasure, cuddliness, duration of orienting, and soothability. While infants are viewed as largely reactive and lacking regulation, their reactive emotional systems do have self-regulatory components. For instance, negative affectivity may regulate/inhibit infants' approach of unfamiliar objects that may be potentially dangerous.

With the development of motor, cognitive, emotional, and language abilities, temperament in childhood and adulthood includes not only three broad temperament dimensions of surgency/sociability, negative affectivity and effortful control, but also a fourth dimension of affiliativeness. These four temperamental dimensions are remarkably similar to four of the Big Five factors, that is, extraversion, neuroticism, constraint/conscientiousness, openness, and agreeableness, found in studies of child and adult personality (Ahadi and Rothbart, 1994; Goldberg, 1993). For instance, surgency/sociability, defined mainly as positive emotionality, sociability, and activity level, resembles the personality factor of extroversion; negative affectivity, defined primarily by the expression of fear, frustration, and sadness, is similar to the personality factor of neuroticism; effortful control, which includes mainly attention regulation and volitional control, is similar to the personality factor of constraint/conscientiousness; affiliativeness has been characterized by prosocial tendencies including empathy or sympathy, and significantly overlaps with the personality trait of agreeableness. With the exception of openness to experience, which has been considered the fifth personality trait in the Big Five factors model, but not a temperamental dimension, there appears to be a strong one-to-one correspondence between temperamental and personality traits in childhood and adulthood (Rothbart et al., 2000). It should be noted that, however, while it may be possible to link affiliativeness to the personality factor of agreeableness, the temperament roots of affiliativeness remain speculative (Nigg, 2006).

Temperamental Contributions to Personality

The underlying biological basis of early temperament, such as the reactivity of the neural system, is relatively stable, and may lead to personality attributes that share similar biological processes. For instance, highly reactive infants, who were easily distressed by novel stimuli, were more likely than their peers to become fearful and inhibited between 24 and 36 months, and to develop anxious symptoms by school age (Kagan and Snidman, 2004). Even a reactive school age child who no longer shows inhibited behavior toward strangers, may still exhibit elevated heart rate during an encounter with a stranger, a physiological response characteristic of temperamental reactivity and the personality trait of shyness (Xu et al., 2009).

Temperament may also contribute to personality through a process of developmental elaboration by which temperamental attributes, as part of individual genetic heritage, accumulate response strength through repeated reinforcement and become elaborated into personality traits, or cognitive and affective representations that are quickly and frequently activated (Caspi and Shiner, 2008). This view emphasizes the transaction between the individual and the environment in maintaining and reinforcing individual differences in how contexts are selected, interpreted, and evoked, and thus producing coherent patterns of continuity between early temperament and later personality. For instance, an inhibited child may actively seek out a nonthreatening environment that does not require intensive social participation, or elicit parents' overly intrusive and protective behavior that inadvertently reinforces the child's shyness or social withdrawal over time (Rubin and Asendorpf, 1993).

While temperament may represent a starting point in development and provides a reaction range for later development, it does not determine the destiny for personality development. Temperamental contributions to personality are

clearly contingent upon socialization experiences, such as parenting and peer relationships. For instance, an early temperamental inclination to negative affectivity might predict later internalization only in children who had a responsive, nonpower assertive mother (Kochanska et al., 1997). Given the importance of socialization, it is not surprising that children with similar temperamental traits develop different personalities, whereas children with distinct temperament show similar personality later in life. Thus, only a small number of inhibited infants remain inhibited over time (Kagan and Snidman, 2004), and children who are initially inhibited could develop either anxiously shy behavior or modest and unassuming behavior, depending on children's effortful control that is susceptible to parenting styles (Zhou et al., 2004).

The Role of Culture

Temperament sets a range of opportunities for development, but culture defines the limit of what is desirable and normal within a particular setting. The transaction between the child and the environment may lead to different developmental outcomes, including personalities, contingent upon the 'goodness of fit' (Thomas and Chess, 1977) between the child's temperament and the environmental demands and challenges that are shaped by cultural values, norms, and socialization goals. Thus, American children with an inhibited temperament often develop anxiously shy behavior, whereas their Chinese peers may exhibit modest and unassuming behaviors that reflect Chinese cultural norms for interdependence and humility (Xu et al., 2009).

Within the goodness of fit framework, personality development is not simply viewed as individual histories of growth, but as forms of mutual adaptation, or the fit between the behavioral expression of early temperament, expectations of significant others such as parents or peers, and the limits of their tolerance for deviance from the behavioral norms (Lerner et al., 1989). Individual attributes that are most strongly associated with negative developmental outcomes are generally those that are inconsistent with local cultural norms.

Personality Development: Systems Theories

Abstract

Developmental systems theories are an important part of modern research of human development. These theories see individuals as a part of a developmental system. The system is composed of the individual and also of the environment. The theories emphasize the holistic principle in research and reject any form of reductionism. Developmental systems theories include dynamic systems theory, developmental contextualism, person–context interaction theory, and holistic, developmental, systems-oriented perspective. Unlike the dynamical systems theory, which is a mathematical construct, the *dynamic* systems theory of Esther Thelen and Linda Smith is primarily nonmathematical and comprises qualitative theoretical propositions in behavioral biology and is the broadest and most encompassing of all development theories.

Systems Theories of Personality Development

Developmental systems theories are an important part of modern research of human development. Their philosophy follows up on the general system theory by Ludwig von Bertalanffy (1968) and is applied to the area of life-span development. They see individuals as being part of a developmental system in their life course. The system is not only composed of the individuals alone but also of the environment in which they develop. These theories emphasize the holistic principle in research and reject any form of reductionism and the traditional input–output model. The system is considered as a whole, which must be examined inseparably, i.e., we examine the individual as well as the environment in which they develop in a gestalt conceptualization. The whole system cannot be broken down into parts; therefore persons cannot be examined in isolation, separately from their environment. If we did that, we would obtain biased and incomplete results. Instead of isolated characteristics (e.g., cognitive development, social development) the theories explore the relationship between system components. By emphasizing the holistic principle they follow the ideas of W. James and J. Dewey, as well as W. Stern, K. Lewin, and G.W. Allport.

In an effort to ensure the most complex possible view of human development they place an emphasis on multidisciplinary collaboration using knowledge not only from developmental psychology but also from other scientific disciplines, such as sociology, evolutionary biology, medicine, and anthropology. Developmental systems theories include dynamic systems theory (Thelen and Smith, 2006), developmental contextualism (Lerner, 1991), person–context interaction theory (Magnusson and Stattin, 2006), and holistic, developmental, systems-oriented perspective (Wapner and Demick, 2003). However, we can find developmental systems perspectives also in other modern theories of development (e.g., Bronfenbrenner, Elder, Brandtstädter).

Probabilistic Epigenesis

The work of Gilbert Gottlieb (1992, 1998) who introduced the concept of developmental systems whereby the changing gene–context or organism–context *relations* are of key importance became an inspiration and a great contribution to the elaboration of systems theories. He applied his theory both in the development and in the evolution analyses. He was inspired by the works of Garstang (1922), de Beer (1958), and Goldschmidt (1933) and points out that the phylogenesis is not the cause but the product of a succession of various ontogeneses, i.e., that variations in the development produce evolution, while evolution does not produce development. "Ontogeny in each generation is a consequence of the coaction of hereditary or genetic factors and many different local environmental circumstances that determine the expression of the phenotype during the course of development" (Gottlieb, 1992, p. 95).

Gottlieb saw the development process as an interrelated, fully coactional system in which the activity of genes can be affected through the cell cytoplasm by events occurring at any other level of the system, including the external environment. He proposed a new definition of epigenesis: "Individual development is characterized by an increase of complexity of organization – i.e., the emergence of new structural and functional properties and competencies – at all levels of analysis (molecular, subcellular, cellular, organismic) as consequence of horizontal and vertical coactions among its parts, including organism–environment coactions" (Gottlieb, 1992, pp. 159–160).

Horizontal coactions are those taking place at the same level (gene–gene, cell–cell, tissue–tissue), whereas vertical coactions occur at different levels (cell–tissue, behavioral activity–nervous system) and are reciprocal. Genes, which are part of the development system like other components (i.e., cells, tissue, organism), are susceptible to influence from other levels in the course of individual development.

To support his theory, Gottlieb gathered substantial evidence proving that the action of genes (gene expression) was influenced by events at other levels of the development system and that all levels of the system could thus be considered as potentially equal. Genetic activity in itself does not produce the final state of the anatomic and physiological differentiation but requires further intervention from the level above cellular level.

Thus, Gottlieb's developmental systems framework indicates that all organism characteristics (genes, cells, organs) as well as the whole organism operate in bidirectional or

reciprocal 'dynamic interaction' relationship with the context in which the organism is embedded. If the time dimension is added, the result is a multilevel, integrated operation that determines the individual course of development.

Dynamic Systems Theory

Esther Thelen and Linda Smith (2006) derived their dynamic systems theory both from studying the complex and nonlinear systems in physics and mathematics and from the traditions of systematic thinking in biology and psychology. In the most general sense the term 'dynamic systems' refers to systems of elements that change over time. In a narrower, more technical sense, the term 'dynamical systems' refers to a class of mathematical equations that describe time-based systems with particular properties. Unlike the dynamical systems theory, which is a mathematical construct, the dynamic systems theory of Esther Thelen and Linda Smith is primarily nonmathematical and comprises qualitative theoretical propositions in behavioral biology and is the broadest and most encompassing of all development theories.

The theory is founded on two central ideas that are expressed not only in the dynamic systems theory itself but also in the history of research into the development process:

1. Development can only be understood as a multiple, mutual, and continuous interaction of all levels of the developing system, from the molecular to the cultural.
2. Development can only be understood as nested processes that unfold over many timescales from milliseconds to years (Thelen and Smith, 2006, p. 258). Developmental systems theory can be seen as a metatheory, as it can be applied to various animal species, age levels, and areas of development. Equally, it can be used as a specific theory that deals with how people acquire knowledge from their daily activities.

According to Thelen and Smith, the defining feature of development is the increasing complexity of the organism, namely the creation of new forms. Qualitative discontinuity, emergence, epigenesis, some kind of novelty are the essence of developmental changes. Each of developmental transitions involves the emergency of new patterns of behavior from precursors that themselves do not contain those patterns.

In the quest for answers about the sources of developmental change Thelen and Smith reject the 'nature and nurture' explanation but also the interaction position/view. They presume the tradition of systems theories of biological organization that explains the creation of new forms through the self-organization process. By self-organization Thelen and Smith (2006, p. 259) mean a process where the pattern or order emerges from interactions among components of a complex system without explicit instructions from the organism itself or from the environment.

The system levels are conceptualized as more than merely interacting with each other; instead they are seen as integrally fused together. The behavior and its development are interrelated as an ever-changing set of relations and the history of these relations over time (Thelen and Smith, 2006, p. 266). Due to this fusion Thelen and Smith replace the linear system of causality with the nonlinear system in which bidirectional relations within and across the fused levels of organization mutually conditionally change over time.

A key feature of the dynamic system is that many heterogeneous system components (cells, tissues, and organs within the individual and the various aspects of an individual's external context) can be freely combined in a virtually unlimited number of ways. In reality, however, the number of relational patterns is smaller. Order emerges from the system complexity through the process of self-organization. Order emerges from the disparate/heterogeneous parts because the human development is an open system, i.e., a system where energy is consumed by the system and used to establish order within it.

Such integration enables the description of the system by using a smaller number of dimensions or parameters. Such integrative variables that emerge in the open system with the aim to reduce its dispersion and to increase its organization are referred to as the collective variables or order parameters.

The emergence of such collective variables provides for continuity and stability within the system. The system settles into or prefers only a few behavior modes. In the dynamic terminology this behavioral mode is an attractor state, as the system has an affinity to this state (2006, p. 272). But even highly stable attractors are dynamic and changeable. Thus, the system – even though it may seem as such – is not fixed, hardwired or programmed, rather it is softly assembled.

The existence of soft assembly means that the development of a person includes a dynamic link between the system stability on the one hand and the fluctuations around the stability states, i.e., changes that are a source of functional novelty within the system, on the other. The system is reiterative, i.e., each state is dependent on the previous state and this reiterative process occurs at all timescales.

Developmental Contextualism

The theory by Richard M. Lerner (1991, 1998) has its roots not only in nonreductionist systematic theories of biological evolution (e.g., von Bertalanffy, 1968; Gottlieb, 1992) but also in sociologically oriented theories concerned with the influence of social and historical changes on human development (Elder and Giele, 2009). From the perspective of development contextualism, development is a result of changes in the entire development system. It is based on the changing relationships between different levels of organization. These consist of the organism and its biological characteristics that exist in a particular sociocultural and historical environment (Lerner, 1991). The developmental system is (1) plastic and open to change, and (2) the relationship between different levels of the system is reciprocal and, at the same time, they are integrated. Each developmental system is (3) hierarchically organized and embedded in a particular historical period. All systems have (4) a certain degree of generalizability, diversity, and individual differences (Lerner, 1998). All of the described components are closely linked. When examining their development, we cannot view them separately because they are interdependent. This is why Lerner in his theory of developmental contextualism emphasizes an integrated, multidisciplinary approach to the study of life-span development.

Another key idea is the inseparability of the organism from the environment. Individuals and their environment are intertwined in the life course. Therefore, we should not examine them separately because human development always occurs in a specific environment. Developmental contextualism applies these general findings to individuals who live and develop in a variety of family, social, cultural, and historical conditions (Lerner, 1991). The developmental model takes into account individual characteristics (e.g., relations between parent and child) and the characteristics of the society or culture that form the largest part of the environment where the development takes place. Developmental contextualism rejects any dichotomy in developmental theories and social sciences (e.g., nature vs nature, person vs context). On the contrary, it emphasizes their integration (Lerner, 1998).

Holistic–Interactionistic Approach

David Magnusson (1999) in his theory puts an emphasis on the integration of an individual and the holistic approach to examining development. He was not only influenced by other developmental systems theories but also by Gestalt psychology, for example. According to the holistic interactionism human development is based on four pillars: interactionism, holism, interdisciplinarity, and longitudinal study. A person does not exist in the environment merely as a passive object; on the contrary, the individual rather exists as an active and conscious part of the context system. Within the system a person develops and operates as an integrated, comprehensive and dynamic unit. We cannot understand the functioning of the environment without taking into consideration the person in it. At the same time, it is not possible to understand an individual's functioning and development without understanding the environment (Magnusson and Stattin, 2006).

The holistic perspective of development is a consequence of gaps in the research so far. Criticism applies especially to fragmentation (excessive specialization without integration), emphasis on variables, prediction (the principal objective of examining personality), unidirectional causality, prevalence of statistics over analysis of the phenomenon and an insufficient link between theory and empirical research. On the other hand, the holistic view describes personality as a living, active, and purposeful organism, functioning and evolving as a comprehensive integrated being. The modern holistic interactionism follows the classical interactionism, an approach that emerged in the 1970s (Endler and Magnusson, 1976).

According to the interaction theory the developmental system functions as a whole. The features of the totality are a result of interactions between all parts of the system. Simpler processes taking place in the system (such as emotional changes) take less time than more complex processes (such as changes in the relationship between the person and the environment). In the life course the system undergoes constant restructuring at all levels. Any process taking place within the system, however, is directed by certain laws. Activities of all parts of the system are coordinated in such a way that each subsystem works toward achieving the goals of the whole system. In the context of a developing system the holistic interactionism describes the principle of so-called amplification of minimal effects. This principle is related to the long-term influence of marginal deviations from the norms of behavior or appearance of a person. Such deviations can cause reactions from the proximal social environment, for example, social isolation in the group as a result of an aggressive behavior. These reactions from the environment may be one of the sources of recurring malfunction in the interaction between an individual and the environment, which can potentiate the maladaptive behavior to a pathological level (Magnusson and Stattin, 2006).

We can analyze the human behavior and experience from three different perspectives: current (synchronic), developmental (diachronic), and evolutionary. The holistic interactionism focuses on the first two perspectives: current and developmental. The model for current functioning is concerned with why people behave in a certain way, in terms of their current psychological and biological dispositions. Developmental models explain the current functioning on the basis of individual developmental history (Magnusson, 1999). In order to understand the current functioning completely we need to understand the conditions of development.

Environment is a key term in models that deal with the current functioning and development. The holistic interactionism sees the environment as a holistic, integrated, and organized system hierarchically structured (Magnusson and Stattin, 2006). However, the objective environment is not so important; it is more important how it is perceived and interpreted. Individual perception and interpretation of the external world is shaped by the actual (objective) environment. This approach does not evaluate an individual and the environment as isolated elements. It explores the relationship between people and their environment, which they helped to create to some extent (Magnusson, 1999). In the integrated person–context system the person acts as an active agent. This does not mean that we cannot examine its specific characteristics, such as aspiration level, physical performance, or current genesis of emotion. We should, however, include them in the overall functioning of the system and take into account their role in its activity (Magnusson and Stattin, 2006).

Holistic, Developmental, Systems-Oriented Perspective

The theory developed by Seymour Wapner (2000) connects organismic and contextual approach for examining human development. It integrates individuals and their environment into a single unit which it calls the person-in-environment system. It is based on extending the theory of Heinz Werner to life-span development (Valsiner, 2005). In it we find inspiration by the developmental task theory by R.J. Havighurst (1972). It rejects any reductionism, particularly biological. Individual levels of the system differ in their qualities and cannot be reduced to other levels. This approach focuses not only on the development of the child but also on the development in the adult age, social relationships, health problems, changes in the physical environment, cross-cultural psychology, psychopathology, and psychology of organizations (e.g., Wapner, 2000; Wapner and Demick, 2003; etc.).

The three key areas of theory are the holistic approach, assessing development as progressive and regressive changes

in which the orthogenetic principle applies (that describes development as a change from a dedifferentiated to differentiated and hierarchically integrated state of the system; Wapner, 2000), and focus on the entire person-in-environment system. The theory further focuses on the relationship between an individual and an environment (transactionalism) and the active operation of the system in making its experience with the environment (constructivism). It also deals with the diversity of the system, the nature of time and space experience, it takes into account the planning processes and focuses both on the description (structural analysis), and the process (dynamic analysis). Although the approach is distinctly macroscopic, it considers specific aspects of a person and an environment. It describes three personal characteristics: (1) physical/biological (e.g., health, physical performance), (2) intrapsychological (e.g., self-respect, self-esteem, stress), and (3) social and cultural (e.g., adoption of a child, social role). Similarly, the environment contains three characteristics: (1) physical (e.g., natural disasters, buildings), (2) interpersonal (e.g., the nature and development of friendship), and (3) social and cultural (e.g., rules, laws) (Wapner and Demick, 2003).

The process of development takes place in such way that the system configuration changes. As a person gains experience and new skills, the structure and function of the system changes. With new experience and skills the system differentiates (becomes more complex), becomes arranged hierarchically and, at the same time, is being integrated. Some system changes are almost imperceptible; others are very important and crucial for development. This theory deals only with those transitions that are critical for an individual. Critical life transitions are of key importance, as they are an opportunity for a change in the behavior and experience of the individual. They come at any age. Many events are significant subjectively, so what is critical for one person is not necessarily critical for another. On the other hand, there are situations, which generally form the basis for critical transitions. These are changes such as the birth of the first child, divorce, adoption, functioning of the family, loss of a partner, retirement or going back to school (Wapner, 2000).

Future Directions

An important initiative of developmental systems theories authors is an effort to interlink knowledge at the level of theory and empirical research but also to find their use in social policies and programs (e.g., Lerner, 1998; Magnusson and Stattin, 2006). These researchers also promote the extending of research boundaries into human development because nowadays the knowledge limited to developmental psychology is not sufficient for a complete understanding and explanation of the developmental process. It is crucial to obtain knowledge in other sciences, such as evolutionary biology, developmental psychology, physiology, anthropology, social psychology, and other related disciplines that make up the so-called developmental science (Magnusson, 1999; Hartup, 2002). A considerable expansion of developmental science took place in the mid-1990s and it is no coincidence that many researchers exploring developmental systems are notable promoters of these ideas. They are those who promote the need for multidisciplinary research. It is only natural that a systematic research into the theoretical and empirical levels of developmental science is associated with a remarkable progress in the quantitative statistical approach, which is connected mainly with the longitudinal methods. They are important for assessing the changing relationship between people and their environment. In addition, the importance of qualitative methods is growing as a valuable analytical tool for assessing an individual life course and as a means of triangulation of the quantitative evaluation of human development. In connection with progress in human development research a growing number of scientists prefer to use the term developmental science instead of developmental psychology (Lerner, 2002; Damon and Lerner, 2006; Lerner et al., 2011).

Abstract

In the twenty-first century, behavioral genetic research has broadened our knowledge about the origins of personality differences and development. On average, genetic factors account for more than 50% of the variance in accurate measures of personality traits. However, heritability estimates of personality traits steadily decrease with age. Genetic factors represent the primary source of long-term continuity of individual differences in personality, but also account for change – particularly in younger ages. On the other hand, environmental factors represent the primary source of personality change in every period of life, but also contribute to the relatively high stability of personality differences throughout the adult life span.

Introduction

Behavioral genetic research on the nature and nurture of personality differences and development has made important progress during the last decades. This review article presents major findings on the influences of genetic and environmental factors on individual differences, stability, and change in personality traits. For that purpose, we first give a short definition of personality traits. We then present an overview of findings from recent behavioral genetic studies on individual differences in personality traits. Third, we review findings from longitudinal behavioral genetic studies on personality development in different periods of life. In addition, we illustrate how these findings can inform different theories on the nature and the nurture of personality development. Finally, we outline implications and provide an outlook on present trends in the fields of quantitative and molecular genetics.

Personality Traits

In this review article, we focus on traits as basic characteristics for the description of personality differences. Personality traits are commonly defined as relatively stable patterns of thoughts, feelings, and actions in which each individual is different from the others. That is, personality traits are fairly stable over time and across situations but still open to change. Personality traits primarily represent economic units of analysis of individual differences in stylistic and regulatory aspects of cognitions, emotions, motivations, and behavior. They do not include broad-sense individual differences, such as physical features (e.g., attractiveness) or abilities (e.g., intelligence).

The Big Five trait taxonomy is the most influential conceptual model that captures personality traits along five dimensions of individual differences (John et al., 2008). Although the five dimensions have been labeled in many different ways, a common characterization employs the following labels: (1) *neuroticism* versus *emotional stability* or *negative emotionality*; (2) *extraversion* versus *introversion* or *positive emotionality*; (3) *openness to experiences* or *intellect*; (4) *agreeableness*; and (5) *conscientiousness* or *constraint*. The Big Five trait taxonomy appears to capture the trait landscape as portrayed in many different languages, societies, and cultures (McCrae and Costa, 2008). It is useful to integrate various systems and major inventories of personality description in terms of temperament and personality traits in a common framework (John et al., 2008). Each of the five traits hierarchically subsumes a set of more specific traits (e.g., anxiety, impulsiveness, gregariousness, activity, altruism, straightforwardness, dutifulness, achievement striving, and openness to feelings or ideas). This hierarchical model is called five-factor model (FFM) of personality.

The Big Five (or FFM) traits predict several specific behaviors, such as tobacco consumption, as well as important life outcomes, such as occupational success, divorce, or even mortality (Roberts et al., 2007). Therefore, the Big Five traits are typically conceptualized as core characteristics – the essential (i.e., the genetically anchored) basis of personality (McAdams and Pals, 2006; McCrae and Costa, 2008).

Genetic and Environmental Influences on Personality Differences

According to the theory that Big Five personality traits reflect genetically anchored core characteristics of personality, several studies have found that individual differences in personality traits are substantially genetically influenced (Johnson et al., 2008). Moreover, the hierarchical structure of the five-factor model "has a solid biological basis and may represent a common heritage of the human species" (Yamagata et al., 2006: p. 987). In their meta-analysis, Johnson et al. (2008) reported that genetic factors accounted for about 50% of the variance in primarily self-rated Big Five personality traits. The remaining variance was primarily due to environmental influences that were not shared by individuals and by family members raised within the same family (see **Figure 1**).

After correction for variance due to random error of measurement and rater-specific perspectives (e.g., self-perspective or well-informed peers), estimates of heritability for personality traits (i.e., estimates of the degree to which individual differences in traits are due to genetic differences) are often considerably higher (Kandler et al., 2010b; Riemann

and Kandler, 2010). Genetics factors accounted for more than 50% of individual differences in these more accurate personality trait scores (compare **Figure 2**(a) with **2(b)**). In a similar vein, the proportion of individual differences in personality traits that was stable over time (Bleidorn et al., 2009) and across situations (Borkenau et al., 2006) showed larger genetic influences that accounted for about two-thirds of the variance in consistent trait scores (see **Figure 2(c) and 2(d)**). Moreover, after correction for random and nonrandom error of measurement as well as occasion-specific and short-term stable influences (<7 years), genetic factors accounted for nearly 100% of the variance in long-term stable (>12 years) personality trait scores (see **Figure 2(e)**), particularly in young adulthood (Kandler et al., 2010a). These findings are in line with the conceptualization of Big Five personality traits as genetically anchored core characteristics of personality.

Genetic and Environmental Influences on Personality Development

Although individual differences in the Big Five traits are fairly stable over the adult life span, recent studies have found

a reversely U-shaped pattern for the degree of stability of individual differences (i.e., rank–order continuity) from young to old age (e.g., Lucas and Donnellan, 2011). That is, the rank–order continuity tends to be relatively low in childhood (4-year test–retest correlations < 0.60), but rises across adolescence and young adulthood reaching a plateau between the ages of 40 and 70 (4-year test–retest correlations range between 0.60 and 0.80). Beyond age 70, the rank–order continuity appears to decay, again (4-year test–retest correlations < 0.60). Moreover, the continuity declines as the time interval between measurements of personality increases. Most longitudinal studies with at least four times of measurement suggest a gradual decline in rank–order continuity (Fraley and Roberts, 2005). However, the rank–order continuity does not decline to zero but reaches a positive asymptote of about 0.40 (Fraley and Roberts, 2005). These patterns of stability (or instability) of individual differences in personality traits over time suggest that (1) personality can change at every age throughout the life span and (2) the most pronounced changes occur during young and old ages. But what are the sources of these changes?

Genetic Set-Points and Environmental Fluctuation

The classic genetic set-point theory that is also known as the dynamic equilibrium model (see Ormel et al., 2012 for a review) attributes long-term rank–order continuity of personality traits to individual differences in genetically driven immutable individual set-points. Environmental influences are assumed to represent situational or short-term stable factors affecting reversible changes or fluctuations around these set-points. That is, on the long run, individuals' personality traits will always regress to their enduring set-points.

According to this theory, an enhanced frequency of environmental fluctuations can be expected during early and late adulthood that can explain the reduced rank–order continuity at these ages (see **Figure 3**). In fact, adolescents and young adults experience more positive and negative life events than do middle-aged people (Kandler et al., 2012). Life events are linked to major changes in life circumstances and social roles (e.g., moves, several graduations from school, apprenticeship, or university, and start an own family). These changes in life circumstances may be associated with reversible changes in personality traits. Life events may change the daily routine of individuals and require new behavioral responses and individual adaptations. Older adults also report more changes in life circumstances (e.g., retirement, death, and illness of close relatives or peers) than mid-adults (Plomin et al., 1990). Yet, on the long run, personality scores of individuals should return to their dispositional set-points accounting for the long-term rank–order continuity of personality traits.

The classic theory of genetically driven immutable set-points and environmental fluctuation, however, cannot explain the steady decline in rank–order continuity over time (Fraley and Roberts, 2005). In addition, this theory cannot explain systematic mean-level age trends; that is, increases in agreeableness and conscientiousness or decreases in neuroticism from adolescence to middle adulthood (Roberts et al., 2006). These findings contradict the assumption of genetically driven set-points that are immutable.

Genetic Continuity and Biological Maturation

Similar to the dynamic equilibrium model, McCrae and Costa (2008) attributed continuity in personality traits to genetic sources. In their five-factor theory (FFT), they explain age trends and rank–order change in FFM personality traits by genetically predisposed maturation processes, in particular in the first decades of life. They do not negate environmentally driven long-term changes, but they claim that maturation is largely independent of environmental influences and that external factors only manifest through biological changes (see **Figure 4**). This theory can explain long-term mean-level changes as well as changes in individual ranks.

Figure 3 This figure illustrates how the genetic set-point theory can explain that rank–order continuity is lower in younger and older ages. Dotted lines represent the immutable set-points of three persons. Continuous lines reflect environmental fluctuations round these individual set-points that are more pronounced in younger and older ages.

Figure 4 This figure illustrates the major claims of the theory by McCrae, R.R., Costa, P.T., 2008. The five-factor theory of personality. In: John, O.P., Robins, R.W., Pervin, L.A. (Eds.), Handbook of Personality: Theory and Research, third ed. Guilford, New York, pp. 159–181. Regarding the sources of continuity and change in personality traits. While genetic and biological factors contribute to both continuity and change, environmental factors can only unfold their influences through biological changes.

Figure 5 This figure illustrates the major claims of the socio-genomic theory by Roberts, B.W., Jackson, J.J., 2008. Sociogenomic personality psychology. Journal of Personality 76, 1523–1544. Regarding the sources of continuity and change in personality traits. Both genetic and environmental factors contribute to personality continuity, whereas environmental factors contribute to personality change both directly and mediated by biological changes.

In line with the FFT, mean-level trends are largely similar across several nations and cultures (McCrae et al., 2005). Also in line with the hypothesis of genetically driven maturation, several longitudinal behavioral genetic studies on personality stability and changes in childhood, adolescence, and young adulthood have found a non-perfect genetic continuity of personality differences (e.g., De Fruyt et al., 2006; Gillespie et al., 2004; Hopwood et al., 2011; Spengler et al., 2012). This reflects genetically mediated changes in individual ranks during this period of life (Kandler, 2012).

Even though rank–order continuity in personality traits are mainly due to genetic sources, environmental change, however, can also become manifest in long-term rank–order continuity ($\geq$10 years), in particular in middle adulthood (Bleidorn et al., 2009; Kandler et al., 2010a). Environmental influences may accumulate throughout the life span leading to a decline in heritability of personality traits with age (Kandler, 2012). A recent study also found systematic cross-cultural differences in age trends in personality traits that can be linked to the normative duration of education in the respective countries (Bleidorn et al., 2013). These findings contradict the assumption of internally driven maturation of personality traits that are largely independent of environmental influences.

Genetic and Environmental Continuity and Social Maturation

In contrast to FFT, many other theories stress the importance of environmental influences on personality stability and change over the life span. For example, socio-genomic theory of personality by Roberts and Jackson (2008) states that the observed continuity of individual differences in personality can be explained by both genetic as well as environmental factors, in particular social factors (e.g., continuity in social roles). This theory explains personality change by environmental processes (e.g., changes in individual life conditions due to major life transitions or changes in social roles) (see **Figure 5**).

Consistent with this perspective is the fact that major familial and occupational roles are largely stable in middle adulthood. This accounts for the relatively high stability of personality differences in this period of life. Furthermore, there are normative biosocial transitions (e.g., puberty, leaving parental home, graduation from school, apprenticeship, or university, starting a family, menopause, or retirement) in each period of life and there may occur life events with positive (e.g., birth of own child or raise of salary) and negative consequences (e.g., accident or layoff) that may lead to changes in social roles, individual living conditions, and new persistent demands on the individual that can explain enduring personality changes in every age (Roberts et al., 2008). The increase of personality stability from childhood to adulthood may reflect a process of social maturation – the development of, committing to, and maintaining an identity that is functional and integrated in its social community, society, and culture. In line with this position is the finding that the increase of rank–order continuity of personality traits in middle adulthood is, in fact, attributable to stabilizing environmental influences (Kandler et al., 2010a).

Social maturation alone, however, cannot explain the consistent findings of non-perfect genetic continuity of personality differences from childhood to young adulthood (Kandler, 2012). But instable or changing genetic influences to personality differences in younger ages are explainable by the hypothesis of genetically driven maturation.

An Integrative Perspective on Genetic and Environmental Development

The above mentioned theoretical models provide different perspectives on the sources of personality differences, stability, and change. Whereas the dynamic equilibrium model and FFT attribute long-term rank–order continuity in personality traits to genetically anchored immutable set-points, the socio-genomic model allows for experience-dependent long-term personality stability. Whereas FFT mainly attributes personality change to genetic and biological sources, the socio-genomic model primarily explains change by environmental sources that become manifest in individual states or social roles and have to be stable or reoccur for a while before they will be permanently anchored in personality traits.

As discussed above, it seems as every single model cannot explain the entire range of empirical findings. This calls for an

integrative model that allows for genetic and environmental continuity as well as genetic and environmental change as a function of age. Such a model can be described in terms of the following five principles that are mainly derived from the empirical findings described above.

1. Genetic factors represent the primary source of long-term continuity of individual differences in personality.
   This principle is consistent with findings that suggest a larger genetic continuity compared to environmental continuity across age (Kandler, 2012). Moreover, it explains the findings of larger genetic contributions to long-term ($\geq$10 years) rank–order continuity of personality traits (Bleidorn et al., 2009; Kandler et al., 2010a). Moreover, a stable genetic core may account for the positive (non-zero) asymptote to which rank–order continuity declines as the time interval between measurement occasions get longer (Fraley and Roberts, 2005).

2. Environmental conditions and related personality-relevant life experiences are more stable in middle adulthood than in younger and older periods of life.
   This principle is in accord with the finding that environmental continuity of personality differences is larger in middle adulthood than in other life phases (Kandler, 2012). The high environmental continuity (e.g., in familial and working contexts) accounts for the relatively high plateau of rank–order continuity of personality traits between the ages 40 and 70 years (Lucas and Donnellan, 2011).

3. Genetic (or biological) maturation can account for personality change in childhood, adolescence, and young adulthood.
   This principle explains the non-perfect but increasing genetic continuity in the first decades of life until perfect genetic continuity is reached in middle adulthood (Kandler, 2012). Universally similar maturation processes in personality may account for similar age trends across different cultures and societies (McCrae et al., 2005).

4. Life experiences (social maturation) can affect personality change in every period of life.
   According to this principle, environmental influences are the primary source of changes in personality traits (Bleidorn et al., 2009). Moreover, environmental contributions (compared to genetic contributions) to individual differences in personality traits increase across the life span leading to a decline of heritability across age (Kandler, 2012). Processes of identity formation that leads to a socially functional and well-adapted personality (i.e., social maturity) may play a major role in adolescents and young adulthood accounting for the increase in environmental continuity across adolescence, young, and middle adulthood (Hopwood et al., 2011; Kandler et al., 2010a). It lies in the human nature to use its natural potentials of learning, self-reflection, and personal enhancement to develop a functional identity that is socially accepted and culturally integrated. Thus, personality maturation may also depend on social and cultural influences (Bleidorn et al., 2013).

5. Complex interplays between genetic and environmental factors contribute to personality development during all phases in life.
   Emerging adults are typically more motivated to choose or change environments that match their genetic predispositions (i.e., niche picking). This may explain the larger heritability estimates for personality traits within the first decades of life (Kandler, 2012). On the contrary, processes of personality adaptation to maintain the created niches and the functional identity are more important in middle and old adulthood. This can account for the shift from the importance of genetic influences to environmental influences on personality differences across adulthood (Kandler, 2012). Most of the reported behavioral genetic findings have relied on twin data. In twin studies, however, interactions between genetic factors and environmental factors are often not taken into account in the analyses of twin similarity (Eaton et al., 2012). If interactions between genetic factors and environmental factors shared by twins reared together are present but not taken into account, these effects would act like genetic influences. Given this interaction plays a major role in the first decades of life when twins share their parental home and other common experiences (e.g., school or cliques), then the contribution of genetic influences to individual differences in personality should be larger in younger ages. This, again, is in line with larger heritability estimates for personality traits within the first decades of life. The other way round, if interactions between genetic factors and environmental factors not shared by twins reared together are present but not taken into account, these effects would be confounded with estimates of non-shared environmental influences. Given this interaction plays a major role in adulthood when twins have left their common parental home and cut their own paths, then heritability should decrease in this period of life. This is in accord with the increasing importance of environmental influences on personality differences across adulthood.

In summary, a model that integrates ostensibly contradicting claims can account for the whole empirical findings. Personality development is a very complex affair. We can only understand the complete picture, if we focus on both genetic and environmental sources as well as the complex interplay between them.

Outlook on Present and Future Trends

Future Studies on Personality Differences and Development

Many of the findings we referred to above refer to only a few broad personality traits, primarily neuroticism and extraversion. It remains an open question whether we can find the same patterns and sources of continuity and change across the life span for other personality traits, such as openness, agreeableness, conscientiousness, or more specific personality facets.

With respect to broad-sense personality, there are interesting differences between personality traits and abilities regarding the relative contributions of genetic and environmental influences to individual differences over the life span. Whereas heritability increases for abilities across age (Briley and Tucker-Drob, 2013), heritability of traits appears to decrease in adulthood. Maybe, there are different processes

involved in the development of traits and abilities (Kandler et al., 2013). This needs to be addressed directly in future studies.

A related question is which patterns of genetic and environmental continuity and change we can find for other personality characteristics that are associated to some degree with the Big Five traits and cognitive abilities, but represent other attributes with more motivational content (e.g., self-related and social attitudes, values, motives, needs, and interests). Future studies should invest more efforts to study the nature and nurture in the development of these characteristics.

Bridging of Quantitative and Molecular Genetic Studies

There is still a large discrepancy between the quantitative genetic findings of large heritability estimates for personality traits and the inconsistent and less replicable findings of very small effects of gene variants accounting for personality differences from the field of molecular genetics. This is often called the missing heritability problem. How can we overcome this large discrepancy? In the following, we provide several hypotheses that need to be investigated by future research.

First, developmental behavioral genetic studies suggest that some genetic factors may emerge in specific ages and that heritability appears to vary across age. Therefore, age differences have to be taken into account in molecular genetics' association studies.

Second, most large genome-wide association scan (GWAS) studies on personality differences rely on short and unreliable measures of personality traits. Since heritability estimates increase with accuracy of measurement (Kandler et al., 2010b; Riemann and Kandler, 2010; Kandler et al., 2013), molecular genetic studies should be able to use more reliable and valid measures of personality traits. For sure, this may be useful to catch more robust gene effects on the level of candidate genes or even single nucleotide polymorphisms (SNPs).

Third, personality traits may be affected by multiple gene variants with very small and statistically insignificant effects. In line with this consideration, a recent study has found that common SNPs – that is, the additive combination of the smallest gene units that vary among individuals – can explain 12% of the variance in extraversion and 6% of the variance in neuroticism (Vinkhuyzen et al., 2012).

Fourth, heritability estimates often stem from studies on within-generational relatives (e.g., twins and other siblings). These estimates include variance due to the nonadditive combination of gene variants that vary among individuals within gene loci (i.e., allelic dominance) or between gene loci (i.e., epistatic gene interactions). Since twin studies have often found higher heritability estimates on the basis of twin similarity compared to adoption or pedigree studies on personality similarity among other family relatives (Vinkhuyzen et al., 2012), this speaks for epistatic gene interactions that are only shared by monozygotic (genetically identical) twins. Epistatic interactions are hard to identify and its effects are even harder to replicate. From these four points of view, the discrepancy between quantitative and molecular genetics regarding the amount of genetic influences on individual differences in personality is not surprising.

Manifestations of Environmental and Epigenetic Factors

Behavioral genetic research suggests that nurture is primarily individual-specific. That is, environmental influences are primarily not shared by family members raised within the same family. Effects of specific environmental variables (e.g., life events) are typically relatively small, accounting for less than 2% of individual differences in personality traits (e.g., Kandler et al., 2012). This displays a parallelism to the missing heritability problem we, therefore, call the missing environmentality problem.

As a parallelism to multiple gene variants with very small and statistically insignificant effects, specific environmental variables alone may have negligible effects. In line with this perspective aggregates of several environmental variables can account for about 13% of the variance in individual attributes (Turkheimer and Waldron, 2000). In addition, as a parallelism to the role of epistatic gene interactions, several environmental factors may affect some but not all individuals and they may interact with other experiences.

Finally, twin studies on epigenetic effects indicate that epigenetic imprinting (e.g., DNA-methylation or histone-modification) can account for differences between monozygotic twins' gene expressions (see van Dongen et al., 2012 for a review). Not surprisingly, epigenetic differences show a small heritability of less than 10%. That is, epigenetic effects primarily reflect individual-specific environmental influences. Epigenetic effects may increase over the life span (epigenetic drift). This epigenetic drift can mirror the increase of environmental contributions to the variance in personality traits across the life span on the level of gene expression.

Conclusions

Behavioral genetic research on personality has made enormous progress within the last decade. We have learnt a lot about the genetic and environmental contributions to personality differences, stability, and change. Genetics factors account for about 50% of the variance in personality self-reports. However, heritability estimates are often considerably larger for more accurate, cross-time stable, and cross-situations consistent with measures of personality traits. Genetic factors represent the primary source of long-term continuity of individual differences in personality, whereas the stability of environmental factors increases until middle adulthood. Environmental sources affect personality change in every period of life, but genetic factors can also explain change in childhood, adolescence, and even in young adulthood. Finally, heritability of personality traits steadily declines in adulthood that is completely different to the well-known trend for cognitive abilities. These findings have helped to integrate ostensibly contradicting theoretical models by formulating five principles of the nature and the nurture in personality development that fit the empirical results. There are still many open questions that need to be answered by future research. Two broad areas of for future research are the missing heritability and environmentality problems that need to be addressed by future behavioral genetic studies.

Abstract

Personality disorders are the most common disorders in the general population and also show overlap (comorbidity) with other mental disorders. As a consequence between 40% and 90% of patients seen in psychiatric practice have personality disorder. The term 'personality disorder' has a long history. It developed from the concept of psychopathy as a degenerative disorder from the opinions of French, German, and Anglo-American psychiatric traditions. Now it is realized that sociocultural factors are much more important than previously suspected, even though around half of normal personality characteristics are genetically determined. Modern classification systems (the proposed ICD-11 and DSM-5) have tried to break out from the somewhat unproductive categorical system of pejorative named disorders that have no external evidence of support for their separation. Only borderline and antisocial personality disorders are used commonly in practice, and this is probably because they are prominent in more severe personality disorders. In this article the current state of classification, treatment, and course of personality disorders is outlined; there is ground for some optimism.

General Considerations

Until the 1980s, both the scientific and the therapeutic aspect of personality disorders were neglected in both practice and research despite their great significance for clinic and practice. Since the introduction of separate Axis II personality registration used in DSM-III (American Psychiatric Association, 1980) and the subsequent editions, DSM-III-R and DSM-IV (American Psychiatric Association, 1987, 1994), research and publication worldwide have prospered, with the introduction of professional journals and scientific societies devoted solely to the field of personality disorders. But there is also much dispute in the field. Now, at the beginning of the twenty-first century, there is a veritable deluge of theoretical concepts of personality and therapeutic interventions, each vying with each other for attention and support despite little evidence that one or more is superior to any other. The alternative more positive way at looking at the field is to congratulate the participants as there are many runners and conclude with Lewis Carroll – "Everyone has won and all shall have prizes."

More than in any other area of psychiatry, this has been a field dominated by opinion and dogma, and hard data on nosology, etiology, and pathogenesis of the alleged individual personality disorders remaining elusive. There is indeed a wealth of isolated facts about the etiological and pathogenetic factors that influence personality traits, but a comprehensive theoretical or empirical model remains as elusive as ever. It is only possible to address certain points and make some qualified references, as the exceedingly complex nature of the subject still does not allow anymore definite statements. In this account there are some contentious points made; the author considers there is more evidence in their support than the alternatives.

'Personality disorder' remains the only term that is widely used and which encompasses all those deviations from a normal personality development that require treatment. There are, necessarily, fluid borders to mental health on the one hand and mental disorder on the other.

Concepts with meaning similar or identical to personality disorder are psychopathy, abnormal personality, psychopathic development, psychopathic or dissocial personality, sociopathy, and personality difficulty.

History of the Concepts of Abnormal Personality

The concept of personality disorder is closely linked to 'psychopathy' (a confusing term as it now refers to the antisocial spectrum only) and comes from French, the German, and the Anglo-American psychiatric traditions.

French Concepts

Pinel's (1809) concept of *manie sans délire* includes instances of 'deranged personality' and can be looked upon as the beginning of the scientific study of personality disorder as a nosological entity. In the eighteenth century, all mental diseases were regarded as fundamental disturbances of the intellect. Pinel was one of the first to point out that in some disorders, the emotions were primarily involved. Nevertheless, the early nineteenth-century definitions of madness remained centered mostly around intellectual function.

Esquirol (1838) developed the concept of monomania, a diagnostic category based on the partial, primary – and independent – involvement of the intellectual, emotional, and/or volitional functions of the mind, including states where a single behavioral disturbance became the sole diagnostic criterion for the condition (e.g., pyromania or kleptomania). Not surprisingly, monomania was one of the sources of the concept of psychopathy. Since its inception, the concept of monomania has been criticized on clinical and medicolegal grounds both in France and abroad.

Morel's (1857) idea of degeneration was a pseudobiological account strongly tinged with the idea of original sin. He proposed that (1) degenerative alterations are

pathological deviations from the normal; (2) mental illness is mostly hereditary; and (3) degeneration is both quantitative and qualitative, that is, new disorders may appear. According to Morel's model, all types of mental and neurological disorders can be traced back to one common hereditary origin. His idea of progressive and polymorphic degeneration was accepted as an explanation of mental illness.

Anglo-American Concepts

Prichard (1835) defined moral insanity as "madness consisting of a morbid perversion of the natural feelings, affections, inclinations, temper, habits, moral dispositions and natural impulses without any remarkable disorder or defect of the interest or the reasoning faculties, and particularly without any illusion or hallucinations." During the early nineteenth century, the word 'moral' had many uses, in the psychological sense chiefly to denote the affective and the conative (rather than the purely intellectual) functions.

The British concept of psychopathy was further shaped by D.K. Henderson (1939), who saw 'psychopathic states' as a condition of 'constitutional abnormality.' In contrast to other (especially German) psychiatrists, he thought of constitution as deriving from both heredity and environment. There were three psychopathic states: the predominantly aggressive, the inadequate, and the creative. The former two were characterized by antisocial traits and soon became part of the Anglo-American concept of personality disorder.

Rush (1812) was the first American psychiatrist to study individuals whose disturbances were primarily characterized by irresponsibility and aggressiveness; who showed, as he put it, a "moral alienation of the mind." He believed that these reprehensible acts were the manifestations of mental disease that they were unmotivated and driven by 'a kind of involuntary power.'

Partridge (1930) defined the concept of psychopathic personality as a persistent maladjustment which cannot be corrected by ordinary methods of education or by punishment. From Partridge on, the emphasis has been on description, and etiological speculation has taken the back seat. To this day, a view of psychopathy as sociopathy dominates Anglo-American psychiatry. A parallel concept, that of the antisocial personality disorder, appeared in DSM-III (APA, 1980) and was retained in DSM-III-R (APA, 1987) and DSM-IV (APA, 1994).

German Concepts

In Germany, the concept of psychopathy embraces most forms of abnormal personality. The current German definition can be traced back to Koch, whose monograph *Psychopathische Minderwertigkeiten* [Psychopathic Inferiorities] (1891–93) was as decisive in shaping the concept of abnormal personality in Germany as Pinel's work was in France, Rush's in the USA, and Prichard's in Great Britain. German ideas of psychopathy also influenced French and Anglo-American views, especially after the 1930s, when many German-speaking psychiatrists and psychoanalysts emigrated to these countries.

Kraepelin's concept of psychopathy, influenced by the French theory of degeneration, formed the basis of Kurt Schneider's typology, and via the latter, of today's German doctrine of psychopathy. In successive editions of his textbook, Kraepelin elaborated on his concept of 'psychopathic states' as abnormal personality. He employed the term 'psychopathic personalities' in a predominantly social sense, including also innate delinquents, unstable liars, swindlers, and pseudo-querulous individuals.

During this period, there also appeared various 'systematic' typologies to draw 'psychopathic' categories from prototypic personality theories. Foremost among these is Kretschmer's *konstitutionstypologisches Modell* (1919). He suggested a specific correlation between body type and personality. Kretschmer (1921) and Ewald (1924) also introduced the concept of *Reaktionstypologien* to account for specific styles of dealing with experience. Systematic typologies lost influence after the publication of Schneider's monograph in 1923.

Kurt Schneider is known especially for his famous monograph *Die psychopathischen Persönlichkeiten* (The Psychopathic Personalities) (1923). He moved the area away from a notion that personality disorder was primarily concerned with neurological degeneration or constitutional inferiority and instead defined it as a problem of behavior and relationships. Schneider coined the memorable phase that those with personality disorder 'suffered from their disorder and also caused society to suffer' which emphasized the necessary problematic interaction with others before the diagnosis could be made.

Schneider's influence has been considerable. It is sometimes said that the eminence of a scientist can be measured by the number of years that he is able to hold up progress, and in Schneider's case this has now almost passed its century. Schneider described a set of 'psychopathic' personalities, although this term is confusing because the word 'psychopath' now has a different construction. His main 10 categories were:

- Hyperthymic (now regarded as within the bipolar spectrum)
- Depressive
- Insecure (now termed avoidant or anxious)
- Fanatic (showing some overlap with narcissistic)
- Attention-seeking (directly translated in the word 'histrionic')
- Labile (now called borderline)
- Explosive (equivalent to impulsive in the UCD-10 classification)
- Affectionless (equivalent to antisocial)
- Weak-willed (no obvious equivalent)
- Asthenic (equivalent to dependent)

Only the current paranoid (whom Schneider described as sensitive personalities (*der* sensitive Beziehungswahn), schizoid, and obsessive–compulsive personalities were not described by Schneider. It is clear that he was an excellent observer and describer of personality and its variation.

Borderline Syndrome

The disorder that perhaps lacked good description, and certainly has poor reliability (Standage, 1979) (from Schneider's list) is labile, now borderline, personality disorder. In many ways this is the odd one out as its subsequent development after Schneider's description came from psychoanalysis

rather that descriptive psychopathology. In the famous paper by Hoch and Polatin (1949) the term 'pseudo-neurotic schizophrenia' was used to describe a condition that many now regard as an example of the admixture of anxiety associated with the development of a schizophrenic psychosis. This paper was published at the time (1949) when schizophrenia was a very loose diagnosis in the United States in which any dysfunctional thought could be interpreted in a way to lead to the diagnosis. It was quickly realized that many patients with pseudo-neurotic or latent schizophrenia did not have any psychosis in the conventional sense, but were extremely disturbed in their mental function, with rapid changes in their affective state that were to some extent different from bipolar disorder, were unable to control their mood and emotions (subsequently called emotional dysregulation), had periods of hopelessness and utter despair often leading to suicidal behavior, acting impulsively with subsequent regret, and only occasional brief psychotic episodes. If this condition had been described at any other time, or by any other psychiatric group other than a psychoanalytic one, it would probably have been classified as yet another mental state disorder, but it was instead incorporated into the personality spectrum.

Much of the credit for placing it with the personality grouping came from the pioneering work of John Gunderson, who first described the cardinal features of the borderline syndrome with his colleague Dr Singer in 1975 (Gunderson and Singer, 1975). Otto Kernberg (1985) also reformulated the psychodynamic interpretation of borderline personality disorder as a diffuse system that had few boundaries and allowed people to register their feelings as primitive emotions without apparent constraint or control. The phenomenology of borderline personality disorder was not very different from other mood disorders, but its impact on others was more like that of personality disorders.

DSM-III

By the time of the DSM-III revision of personality disorders in 1980 it was difficult to know where borderline personality disorder, and indeed the other personality disorders, might be placed. In a bold move, that many have seen as political rather than scientific, Robert Spitzer, the architect of DSM-III, offered personality disorders to the psychodynamic lobby of American psychiatrists as a separate axis of classification on the grounds that no other group of psychiatrists would be particularly interested in this diagnosis, and by giving it a separate axis its full implications could be explored independently of any other disorder. This was essentially a trade-off, the resistance of many psychodynamic psychiatrists to DSM-III could be reduced if they then had a condition in which their expertise was recognized to be highly important. However, in what may be a personal minority view, of the personality disorders, it is only borderline personality disorder that is really attractive to psychodynamically orientated therapists, and, in terms of its phenomenology, this disorder is really more of a complex affective state rather than a personality disorder (Tyrer, 2009).

DSM-III finished with a new set of personality disorders and a new classification axis for them (Axis II). But, despite this great achievement all was not exactly well with the new classification. Axis 1 disorders were diagnosed using the operational criteria that had been so influential in defining schizophrenia, depression, and bipolar disorder and to a lesser extent the non-psychotic disorders. This procedure did not work so well with Axis II. Clinicians were not being asked to identify an abnormal mental state with a fixed-time onset and often a short duration, but a continuous problem of relationships and behavior that could not easily be described and accessed in a single interview. An attempt was made to describe typical (prototypic) behaviors that brought out the main features of the personality disorder. For example, one of the criteria for paranoid personality disorder "reads hidden meanings or threats into benign remarks or events, for example, suspects that neighbours put out trash early to annoy them." This is a culturally derived concept that is very difficult to extrapolate to the worldwide stage; how would a paranoid Eskimo or Bedouin nomad score on this particular item? Despite this, DSM-III has dominated personality disorder classification since this time, and the current classification and description are shown in Tables 1 and 2.

Focusing on specific behaviors shows how difficult it is for an assessor to decide whether someone is genuinely paranoid simply by picking on one or two single types of problem and hoping that these can be melded together into an overall condition that will allow the diagnosis of paranoid personality disorder. Short cuts to the diagnosis of personality problems are inherently flawed – rather like guessing the nature of a picture from a thousand-pieces jigsaw puzzle by seeing only twenty of the pieces in their proper position. What is needed is a better overall perspective of the subject, not the exact contours of a few specific parts.

Furthermore, when detailed studies were made of the distribution of the different criteria among the nine personality disorders in DSM-III the real structure was found to be completely different from that of the architects of the individual disorders (Livesley et al., 1994). Clinicians were

Table 1 General diagnostic criteria for personality disorder

1. A lasting pattern of inner experiences and behavior which deviates markedly from the expectations of the culture the individual lives in. This pattern is manifested in two or more of the following areas:
   a. Cognition (i.e., ways of perceiving and interpreting oneself, others, and events)
   b. Emotiveness (i.e., range, intensity, stability, and appropriateness of emotional response)
   c. Interpersonal functioning
   d. Impulse control
2. The pattern is inflexible and pervasive across a broad range of personal and social situations.
3. The pattern leads to clinically significant distress or impairment in social, occupational, or other important areas.
4. The pattern is stable and long-lasting, and its onset can be traced back to adolescence or early adulthood.
5. The pattern is not better accounted for as a manifestation or consequence of another mental disorder.
6. The pattern is not due to direct physiological effects of a substance (e.g., drug or medication) or a general medical condition (e.g., head trauma).

also being asked to make the diagnosis of personality disorder in two stages: (1) the identification of the presence or absence of the personality disorder, followed by (2) the description of the disorder by category. The trouble with this advice was that people were so fascinated by the individual labels of personality disorder that they went straight to the second phase without really considering whether or not the person had a generic personality disorder and satisfied or did not satisfy the descriptions for this. This was also complicated by the consequence, entirely predicted by the empirical evidence, that because the factor structure of the individual categories overlapped, the disorders themselves seemed to overlap to a similar degree. It was therefore fairly rare for a person to have a 'pure' categorical personality disorder without any features of any other. This almost completely nullifies the advantages of a specific categorical label.

Likely Changes in the Classification DSM-5 and ICD-11

The current situation of personality classification can be summarized as the 'Hong Kong problem.' Hong Kong was a part of China but was leased to the British government because it was highly productive and allowed trade that would otherwise have not taken place between China and the rest of the world. It could always be only temporary and now Hong Kong is part of China. Similarly, allowing personality disorder to have its own special axis of classification led to expansion of research and activity in this field but the separate classification was always likely to be 'on loan,' and now it appears that the main body of mental state disorders wants to reclaim personality disorder as its own, and all axes are proposed to be abolished.

This will mean that all mental disorders will be classified in the same group and personality dysfunction may sometimes be forgotten about when it is necessary to make a primary diagnosis only. One of the reasons for providing a second axis of classification, in addition to satisfying the psychodynamic lobby, was to give more attention to conditions that might otherwise be forgotten. There is no doubt that this has been a benefit, as least to researchers, and abandoning it might reduce the profile of personality disorder in the future by relegating it to a secondary position. On the positive side it would allow personality disorder to benefit from the process of nosological inclusion – no longer on the outside of the main system, and possibly reduce the stigma to which this diagnosis is subject, particularly among psychiatrists. But it has to earn its place there and will have great competition. It would help greatly if more than one diagnosis was encouraged as the influence of personality disorder on the outcome of other conditions, as outlined in the following section, can be considerable. What is needed is a simple way of diagnosing personality disturbance that is socially inclusive rather than stigmatizing. This is being attempted in the revision of personality disorder in ICD-11 by a working group on behalf of the World Health Organization.

Introduction and Summary of Current ICD-11 Personality Disorder Proposal

The fundamental changes proposed for the revision of the classification of ICD-11 personality disorders can be summarized as follows:

1. to make the primary classification based on *severity* of personality disturbance;
2. a *secondary classification* of *five trait domains* that qualify the nature of the personality disturbance but which is not essential to the classification;
3. a *simple rating procedure* that allows diagnosis to be made easily both in primary and secondary care (Tyrer et al., 2011).

The DSM-5 proposals for the revision of the DSM-IV classification of personality disorders also regard severity as part of the classification. However, the primary classification is again by category, but into a somewhat smaller group than existed previously. Currently, borderline, schizotypal, narcissistic, avoidant, obsessive–compulsive, and antisocial personality disorders are in the DSM-5 diagnostic frame. The DSM-5 proposal is also likely to be considerably more complex than the ICD-11 proposal, taking up to 40 min or longer to assess properly, and hence there are questions about its clinical utility. Unfortunately, the American Psychiatric Association regarded the complexity overcame its clinical usefulness and currently it is in a new group, that is, Section 3 of the classification (for further study).

The new ICD-11 system abolishes categories of personality disorder and the secondary domains of personality only serve to qualify the classification of severity. Personality status will be classified on five-dimensional levels:

1. No personality disturbance.
2. Personality difficulty (some personality problems in certain situations but not universally) (coded as a Z-code so it does not become a formal psychiatric disorder).
3. Mild personality disorder (definite well-demarcated personality problems across a range of situations).
4. Moderate personality disorder (definite personality problems usually covering several personality domains and across all situations).
5. Severe personality disorder (definite personality problems usually covering several personality domains and across all situations which carry significant risk to the individual or to society).

The adoption of a severity classification does not overcome the need to have a division between those who have personality disorder and those who do not, although the dimensional range makes the point of separation less critical. The critical diagnostic point is reached when there is clear evidence that interpersonal dysfunction is pervasive and persistent, a behavioral and attitudinal fingerprint that shows itself in all situations. The distinction between interpersonal and general social dysfunction is an important one. I personally think that the best definition of interpersonal dysfunction is 'a pattern of general impairment in human relationships that prevents mutual understanding' as it is the lack of mature connection with other people that is the main problem here. This is an attempt to make a clear dividing line between social malfunction occurring as a consequence of other mental disorder and that associated with personality difficulties.

The domains of personality have not yet reached final agreement but are likely to be five: dissocial, detached, disinhibited, negative emotional, and anankastic domain traits (Tyrer et al., 2014) – the externalizing, internalizing, schizoid, and obsessive–compulsive domains. Thus, in describing someone as suffering from a personality disorder currently within the borderline emotionally unstable domain there will only be one diagnosis indicating the severity, and additional diagnostic information such as 'with externalizing and internalizing features.' Thus, the clinician will only be pointing out the features that are most prominent within the severity framework, not fixing on 'borderline' as a descriptor. In ordinary psychiatric practice many of the finer points about the subdivision of the categories of personality disorder – affective instability and impulsivity in *borderline personality disorder*; callousness and irresponsibility in *antisocial disorder*; and dependence and anxiousness in *avoidant personality disorder* – show the lack of sharp boundaries between each of the individual categories. Despite the wish to give them rock-like diagnostic status, the current classification are fundamentally unstable. Trait domains are more secure, but they still overlap, particularly when personality disorder gets more complex and severe, when they end to accumulate the features of other domains.

Mixed and Unspecified Personality Disorders

One of the most serious deficiencies in the current classifications of personality disorder is the very large number of diagnoses that indicate personality disturbance but do not fit the existing categories. These can account for up to a third of all diagnoses.

The proposed ICD-11 classification should help greatly in avoiding the need to use mixed categories. At higher severity levels, mixed personality disorders are the norm. Both complex and severe disorders are likely to exhibit characteristics from more than one domain, and the proposed system offers the opportunity to record the domains that are most prominent. By making the severity level the primary rubric of classification, more complex formulations are kept within the overall structure; everybody with personality disturbance has to be classified at one of the severity levels. In this way, the domains of personality disturbance are essentially qualifiers for personality disorders at a given level of severity. The only time that 'unspecified' would be used is when the severity level cannot be determined.

Why Does the Present System Need to be Changed?

Most clinicians agree that the current system is unsatisfactory in practice (Bernstein et al., 2007) and the criticisms boil down to three issues: (1) the frequent difficulty of making a good fit between patients seen in clinical practice and the formal categorical descriptions; (2) the heterogeneous and shifting nature of personality disturbance, even though personality is meant to be one of the most enduring of human characteristics; (3) the artificial dichotomy between pathology (personality disorder) and health (no personality disorder). Both DSM-5 and ICD-11 agree on this last point, and they introduce dimensions in various ways into the classification.

Clinical Utility – Making a Better Fit

The categories of personality disorder are good for office parties but not for office psychiatry. Some of the more amusing discussions at social occasions where the conversation begins to flag are about the personality characteristics of well-known individuals. Like a moth to a flame, the adjectives 'paranoid,' 'borderline,' 'avoidant,' 'narcissistic,' and 'antisocial' are just too enticing, particularly when they can be applied to politicians, doctors, administrators, and bureaucrats who create annoyance in their different ways. The curious thing is that when clinicians go back to their office they do everything possible to avoid using these terms, even though the pathology is obvious for all to see. There is now good evidence that somewhere between 10% and 20% of patients in primary care and between 30% and 40% of patients attending secondary care clinics in both psychiatry and general medicine have significant personality disturbance when assessed by researchers (Tyrer et al., 2014).

Not only are we very chary of using the diagnosis of personality disorder but we mainly confine our descriptions of personality disorder to three groups: borderline, antisocial, and (in the USA) schizotypal personality disorder. The others are hardly ever used in practice or in research. In the USA there is concern over the possible loss of narcissistic personality disorder and, while the gossipers will doubtless predict this concern as self-fulfilling, since the diagnosis is accompanied by a strong sense of entitlement, this alone is not be a good reason to retain it!

Treatment

One of the reasons why personality disturbance in any form was, and to some extent still is an unpopular diagnosis is that treatment options are limited. But there has been increasing optimism over the past 20 years, even though the gains are still relatively small, as one might expect after a long, and until recently justified, reputation of untreatability.

There are now over 20 treatments competing for treatment of personality disorder.

The biggest impact has been made by dialectical behavior therapy (DBT) in a paper published 20 years ago (Linehan et al., 1991). This unashamedly positive paper, with a well-promoted treatment protocol, was a major influence in persuading clinicians and managed care companies that at least one personality disorder, borderline, was responsive to treatment, particularly in reducing episodes of self-harm. (It is also fair to add that Marsha Linehan, the originator of DBT, does not like the term borderline personality disorder, and prefers the more accurate 'emotional dysregulation disorder'.)

Following the success of DBT, a treatment originally described as a form of psychodynamic psychotherapy linked to day hospital treatment (partial hospitalization), but later relabeled as mentalization-based treatment (MBT) (Bateman and Fonagy, 1999), has been almost as influential. MBT offers a way forward for psychodynamic therapy, then held back by lack of evidence, and this treatment has now been manualized. Transference-focused therapy, based on Kernberg's model, has also shown similar benefit. Cognitive-behavior therapy adapted for personality disorders, and its related treatment, schema-focused therapy, also have published evidence of their efficacy, but despite the high quality of these trials, have not had as much impact as MBT and DBT trials, partly because they were published later and partly because their results are not quite as impressive (Davidson et al., 2006; Giesen-Bloo et al., 2006). More recently, Systems Training for Emotional Predictability and Problem Solving (STEPPS) (Blum et al., 2008) has also yielded good results comparable with other trials. Cognitive analytical therapy has also been widely used, but with limited evidence of efficacy when compared with good standard care. Indeed, when all these treatments have been compared with good standard care their impact, is less impressive and shows that generic aspects of psychological treatments are more important than their specific differences (Bateman et al., 2014).

Other forms of personality disturbance have attracted reduced therapeutic interest. The main reason for this is simple one: a majority of those with any form of personality disturbance do not want to have treatment, irrespective of any value it may have. Type R (treatment resisting) personalities are three times commoner than Type S (treatment seeking) personalities in clinical populations (Tyrer et al., 2003) and nine times commoner in other populations (Gardiner et al., 2010), so it is no wonder that people with these disorders are not flocking to take part in randomized trials or promoting their pathologies. The exceptions are avoidant personalities, mainly because they overlap with chronic social and generalized anxiety, which are associated with Type S, and antisocial (dissocial) ones, who may not want treatment themselves but who have treatment thrust upon them because society demands it. Here the results are equivocal, with the only robust finding being that programs based on punishment are generally less effective than those based on reward (Gibbon et al., 2010). Randomized trials of treatment in this condition are rare but are feasible, and deserve more attention.

There is a form of treatment for the Type R personality disorders too. Nidotherapy (nest therapy), coined and developed by the author, describes the 'treatment,' not of the patient but of the environment, and is named because a bird's nest is an excellent example of an environmental adjustment to suit whatever is placed within it. For people with personality disturbance who have no wish to change themselves, but are only too willing for things to change around them, nidotherapy is an ideal option and has already been shown to be of value in those with comorbid personality disturbance and severe mental illness (Ranger et al., 2009). The aim of nidotherapy is to explore with the patient the opportunities for environmental change and then to plan a course of action with a timetable in order to achieve this. Examples of successful nidotherapy in those with schizoid personality disturbance can include placement in a job that involves no people contact (e.g., night security guard), in those with antisocial personality disturbance (certain roles within armed services), and in those with obsessive–compulsive personality disturbance (all predictable activities requiring careful checking). In all these instances the aim is not to change the pathology but to make it less discordant with the environment.

Outcomes

The discerning reader will realize that the choice of treatment for those with personality disturbance is not a properly informed one. Almost all the treatments that have demonstrated at least some evidence of effectiveness have been compared with no treatment or standard care. When comparisons have been made between active treatments they have shown discordant findings (e.g., Giesen-Bloo et al., 2006), suggesting that the differences are due to the enthusiasm and orientation of the main investigators rather than any intrinsic superiority of one treatment over any other. In complex trials such as these, reporting bias is considerable and has a major impact on the way results are presented. For this reason NICE guidelines (the guidelines of the National Institute of Health and Clinical Excellence in England) for borderline personality disorder recommended *any* well-structured, theoretically driven, psychological program, of long-term duration, for borderline personality disorder. They do not specify any particular treatment, with the exception of dialectical behavior therapy which is undeniably successful in preventing repeated self-harm in patients with this condition (National Collaborating Center for Mental Health, 2009).

We must remember that the public health implications of personality dysfunction are enormous. It is also clear that treatment should ideally be given early in the course of the disorder. Unfortunately, the current diagnostic systems only allow for the diagnosis of personality disorder when a person reaches the age of 18 years, although this is not backed by any empirical evidence. Fortunately, in ICD-11 the age limits have been removed (Tyrer et al., 2014). Many existing diagnostic boundaries (e.g., conduct disorder/dissocial personality disorder and disruptive mood dysregulation disorder/borderline personality disorder) are artificially set by age. Clinicians should have the option of diagnosing personality disorder at any age, including later in life if the problems are sufficiently persistent. There is bound to be some reluctance to use the diagnosis of personality disorder in young people because of its stigmatizing implications, but if we can bring the attribution of personality disturbance away from prejudice and discrimination there is no reason why it cannot be discussed openly and constructively early in life.

Importance of Personality Disturbance in General Psychiatric Management

One of the advantages of having two axes of classification in DSM was the encouragement to make separate mental state and personality assessments when evaluating patients. In practice this is constantly in clinicians' minds when they choose treatment. Therefore, for example, a clinician would rarely give a potentially dangerous drug such as a monoamine oxidase inhibitor to a person with borderline personality disorder, as the risks would be deemed too great, yet would be willing to give a drug such as amitriptyline in gradually increasing dosage involving the monitoring of adverse effects to an obsessional person who liked to keep a constant check on symptoms and monitor them closely. The presence of personality disturbance could, and should, be a guide to both treatment duration and prognosis. There is now good evidence that the outcome of depression is worse in the presence of personality disorder compared with patients with depression and no personality disorder (Newton-Howes et al., 2014), irrespective of the type of personality disorder. If personality disturbance is postulated to be a diathesis in which sufferers are more vulnerable than others to stresses (Tyrer, 2007), it is not surprising that this vulnerability shows itself in repeated episodes of ill health.

The artificial dichotomy in our current classification that requires clinicians to decide who does or does not have a personality disorder also leads many to avoid using the diagnosis altogether. Many service users feel this diagnosis is unhelpful indeed there is a feeling of collective anger against it. One advantages of having a dimensional range of personality disturbance in which the initial diagnosis is as much one of *current* personality function is that both correction and change are implicit in the diagnostic structure. In addition, the capacity for improvement without losing all personality pathology is a better way of assessing progress than the crude attribution of the presence or absence of a personality disorder.

If we abandon the assessment of personality altogether we would lose a large part of the overall diagnostic view of patients, which is tending more and more to diagnose short-term conditions that can be ephemeral and which have little connection with real life-history and continuing problems in living. 'Pack 'em in, treat 'em quick, get 'em out' is often the covert message given to the young psychiatrist of today. The compression of time frames is accentuated by the fragmentation of services, so that it is now rare for patients to have the chance, even if it is wished, to develop a proper relationship with a psychiatrist. The notion of a personality diathesis, in which the mental state pathology of an individual can be predicted in the short and longer term by knowledge of continuing personality structure, is not easy to foster in this climate.

The Future of Personality Disturbance in Diagnostic and Clinical Practice

Whenever a patient presents to a medical or psychiatric service there should be an assessment of personality status. All current forms of assessment are very crude and rely on self-report or the opinions of others, but it is likely over the next few years that simple biological or psychological measures will be found to give an independent assessment of personality status. Why should this not be relevant in all parts of medicine? In my first junior job as an assistant to an orthopedic surgeon I asked my consultant one day why he was recommending surgery to one lady who had the same problem as another one in the adjacent bed, but for whom he was recommending a slow rehabilitation strategy. 'Because she is a tiger,' he replied, 'the other is a lamb.' His personality assessment, rightly or wrongly, had a major impact on his choice of intervention. The same should happen in all parts of medical and psychiatric assessments. We should not only assess current symptoms and function, but also place the person in a wider context so whatever we decide will fit in well with our acute plan of management.

Thus, for example, if a patient presents in a highly distressed and depressed state to an emergency center with suicidal symptoms the treatment should not always focus on immediate suicide prevention. If the patient is a 65-year-old widow whose son has just been killed in a motor accident, and whose previous mental health has been free of concern, the management should be very different from that of a woman of similar age who has a history of recurrent mental illness and four previous suicide attempts. The evaluation of personality is the key to management, not the number of boxes ticked on a DSM depressive symptom checklist.

At the end of the assessment the formulation of any medical or psychiatric problem would include a statement about personality status and its relevance to treatment. It will not only include aspects of personality dysfunction as described above but also personality strengths and advantageous attributes. Even the most skeptical reader will recognize that, whatever their views about personality disorder as a diagnosis, everyone has a personality, a set of characteristics that make them more or less reliable to adhere to treatments, to follow complex instructions, to act with discretion or on impulse, and to collaborate with their fellows or do things in isolation. All complex and persistent diseases such as hypertension, diabetes, and arthritis have a course and morbidity that is determined as much by their personality as by the specific treatment given. By knowing both personality status and the physical or mental pathological state it is possible to combine them to produce the maximum benefit.

Abstract

Behavioral genetic studies have shown that around a third to a half of the between-individual variation in personality traits can be accounted for by genetic differences between individuals. There is rapidly growing interest in understanding the evolutionary basis of this genetic variation. In this article we review the major explanations that have been proposed to explain the evolutionary maintenance of genetic variation in personality. We cover selective neutrality, various forms of balancing selection, and mutation–selection balance, as well as the possibility that personality trait levels are calibrated to the level of other traits that are themselves under mutation–selection balance.

While evolutionary psychology has had success in identifying and explaining many putative species-typical psychological adaptations, a similar understanding of individual differences remains more elusive (Buss and Hawley, 2011; Penke et al., 2007). Many basic human characteristics are universal in the population: Barring accidents, virtually everyone has the same number of eyes and limbs, for example. Such characteristics may have been historically vital to survival and reproduction, or they might be subject to strong developmental constraints. However, the color of eyes or length of limbs does vary between individuals, and virtually all of the 'universal' traits that interest evolutionary psychologists actually differ considerably between individuals. For example, cross-cultural research shows a 'universal' effect whereby men place greater value than do women on physical attractiveness, whereas women place greater value than do men on a partner's earning potential (Buss, 1989). However, despite this consistent mean difference between men and women's preferences, the within-sex variation between individuals is considerably greater than the between-sex difference. Furthermore, this within-sex variation is not just due to random environmental experiences – genetic variation accounts for a substantial proportion of individual-differences in mate preferences (Verweij et al., 2012a; Zietsch et al., 2012) and virtually all other individual-differences that have been investigated (Bouchard and McGue, 2003).

A key evolutionary question is how and why this genetic variation is maintained in the population despite countless generations of winnowing by natural selection. Some individual differences, such as fingerprint ridge count, have negligible fitness consequences. Variation in such traits is easily explained because they are selectively neutral: there is no winnowing effect. But behavioral traits such as personality (i.e., consistent patterns of behavior (Pervin et al., 2005)), pose a conundrum because they seem at face value to comprise behavioral patterns of high relevance to fitness: social boldness versus shyness (extraversion), tendency to cooperate versus compete (agreeableness), emotional volatility versus stability (neuroticism), and so on. Nevertheless, Tooby and Cosmides (1990) made the early and influential argument that the substantial heritability of personality traits is evidence against personality serving an adaptive function, primarily because natural selection works to deplete variation. Given that virtually all quantitative traits (i.e., traits that vary continuously) are substantially heritable, this position suggests that heritable individual differences in general are evolutionarily unimportant; indeed, Tooby and Cosmides (1990) make the argument that understanding the evolutionary basis of species-typical characteristics is far more important than the study of individual differences. The prominence of Tooby and Cosmides in the nascent field at the time meant that their position probably discouraged evolutionary research on personality and individual differences for much of the field's development.

However, the importance of understanding personality and individual differences from an evolutionary perspective has recently been emphasized in both human (Buss and Hawley, 2011; Penke et al., 2007; Verweij et al., 2012b) and animal (Bell, 2007; Dingemanse and Wolf, 2010; Reale et al., 2010) literatures. Understanding the evolutionary basis of individual differences is crucial to understanding the operation of evolution, because genetic variation is the substrate upon which selection acts. For example, mate choice drives sexual selection, and mates are chosen on their *relative* merits based on individual differences in personality, intelligence, physical attractiveness, etc., while species-typical characteristics are invisible (Buss, 2009).

All personality traits exhibit substantial heritability (heritability is the proportion of variation attributable to genetic variation); behavioral genetic studies over more than 50 years indicate that around a third to a half of the variation in personality traits can be accounted for by genetic differences between individuals (Johnson et al., 2008). In contrast, the family environment has a negligible effect on personality variation (Johnson et al., 2008). The persistent heritability of personality traits presents a theoretical challenge, because natural selection typically works to deplete genetic variation (Barton and Keightley, 2002; Fisher, 1930; Merila and Sheldon, 1999). Alleles that increase fitness tend to become fixed in the population, while those that decrease fitness tend to be eliminated. Given this winnowing effect of selection, the question arises as to why heritable variation remains in the population. We review the major explanations that have been proposed to explain this apparent paradox, outlining some of the evidence

for and against each. We cover selective neutrality, various forms of balancing selection, and mutation–selection balance. We also look at the possibility that personality trait levels are calibrated to the level of other traits ('facultative calibration') that are themselves under mutation–selection balance.

Selective Neutrality

Selectively neutral genetic variants are not subject to natural selection because they have no net effect (positive or negative) on fitness. A simple explanation of why heritable variation in personality is maintained is that personality traits do not affect fitness and that the underlying alleles are therefore not winnowed by selection.

However, genetic variants underlying personality traits seem unlikely to be selectively neutral. Personality traits have been shown to influence a number of fitness-relevant outcomes, including mating success (Nettle, 2005), sexual behavior (Heaven et al., 2000; Zietsch et al., 2010), health (Neeleman et al., 2002), longevity (Friedman et al., 1995), mortality (Mosing et al., 2012), parenting (Spinath and O'Connor, 2003), and reproductive success (Bailey et al., 2013; Eaves et al., 1990). Personality also guides behavioral responses to adaptive problems, such as securing resources, selecting mates, or forming cooperative social alliances (Michalski and Shackelford, 2010). Given that personality is closely linked to fitness outcomes, it seems unlikely that it has remained invisible to natural selection.

However, it is possible that personality traits are related to several fitness components in such a way that positive effects on one component of fitness are canceled out by negative effects on other components of fitness, making the effect on overall fitness approximately uniform (selectively neutral) across the normal personality range (MacDonald, 1995). Expanding on this view, Nettle (2005) proposed concrete cost-benefit trade-offs associated with the Big-Five dimensions of personality variation in humans. High extraversion is predicted to confer benefits of increased status and the associated access to resources and mates, but also the costs of an increased propensity for accidents, disease, and social conflict. Nettle (2006) further extended this line of thinking to the other Big-Five traits. He proposed that high neuroticism may provide increased vigilance to threat at the cost of increased stress and mental illness, while conscientiousness may provide the benefit of increased health and longevity at the cost of rigidity and difficulties adapting to a fluctuating environment. Agreeableness provides advantages in social interaction and cooperative ventures while increasing the risk of one being taken advantage of or cheated, and increased openness to experience may provide the benefit of creativity (an intersexually attractive trait) at the cost of susceptibility to disorganized or potentially psychotic thinking (Nettle, 2006).

As such, although personality traits are demonstrably associated with *components* of fitness, it remains theoretically possible that variations in personality traits have no *net* fitness effects once multivariate relationships are factored in. This idea is concordant with the geometric view of adaptation proposed by Walsh and Blows (2009), in which genetic variants affecting multiple traits can be invisible to selection when multivariate genetic constraints result in little or no variation in fitness effects, even when the individual traits correlate with fitness and have substantial genetic variation.

However, the genetic architecture of selectively neutral traits is expected to match the distribution of allele frequencies that arises from pure genetic drift (i.e., no selection). For a trait under no selection, the distribution of the additive genetic variance explained as a function of minor allele frequency (i.e., the frequency of the less common of the two alleles) is expected to be flat, so that every minor allele frequency range of the same width accounts for the same proportion of variance in the trait (Eyre-Walker, 2010). As such, the vast majority of the genetic variance in a selectively neutral trait should be accounted for by common variants (i.e., variants in which the minor allele is not rare in the population). This is not the case for personality traits, of which most of the genetic variation is not accounted for by common variants (Verweij et al., 2012b; Vinkhuyzen et al., 2012). Further, Verweij et al. (2012b) show that personality traits are impacted by inbreeding, which is predicted of a trait that has been under directional selection, but is not expected for a selectively neutral trait. These findings suggest that genetic variation in personality traits is unlikely to have been maintained due to selective neutrality.

Balancing Selection

An alternative possibility is that selection actively maintains (rather than depletes) variation in personality. This can occur when selection pressures vary across different contexts (Hedrick, 2007). It should be well noted that the presence of context-dependent selection pressures does not necessarily imply that balancing selection is maintaining genetic variation – balancing selection can only maintain genetic variation under quite restrictive conditions (Turelli and Barton, 2004). There are a number of mechanisms of balancing selection, including spatiotemporal environmental heterogeneity, sex-dependent selection, frequency-dependent selection, and heterozygote advantage.

Spatiotemporal Heterogeneity

An intuitively appealing form of balancing selection is caused by selection pressures that vary across space and time – this is called spatiotemporal heterogeneity (Buss, 2008). It is easy to imagine that optimum personality trait values would vary with the environmental conditions, such that the fitness value of a given personality trait will be higher or lower depending on the prevailing niche. For example, relatively safe and stable environments may favor a bold and exploratory personality, while high-risk environments may favor a more conservative and cautious type (Reale et al., 2010). Variation in personality can in theory be maintained when there is no one optimum – different alleles are favored in different environments and so multiple alleles can be maintained in the population.

Several empirical studies have indicated that differential environmental selection pressures produce different personality profiles in both humans and nonhuman animals. Dingemanse et al. (2004) tested the impact of fluctuating

selection pressures on the 'personalities' of great tits, comparing 'fast' exploring, aggressive, and bold birds with 'slow' exploring, nonaggressive, and shy birds. Dingemanse et al. (2004) showed that fluctuating selection pressures influenced male and female birds differently. Rich years favored slow exploring females, while poor years favored fast exploring females. Conversely, fast exploring males benefited in rich years, while slow exploring males were favored in poor years. This suggests that the selection pressures produced by a fluctuating environment could potentially maintain variation, as no one personality phenotype is at a clear advantage or disadvantage to any other type.

Camperio-Ciani et al. (2007) conducted one of the few empirical tests of the effect of varying socioecological niches on the personality profile of a human population. They compared the personality of individuals living on a series of culturally and geographically similar islands off the coast of Italy with their corresponding mainland populations. When compared to mainlanders, the island inhabitants demonstrated higher conscientiousness and emotional stability, but less extraversion and openness to experience. Emigrants who left the island for the mainland scored higher on measures of extraversion and openness than those who had never left the island. Camperio-Ciani et al. (2007) concluded that the significant personality differences between islanders and mainlanders were indicative of genetic adaptation to the particular socioecological niche of the islands.

In a similar vein, Schaller and Murray (2008) investigated the effect of variations in pathogen prevalence on the personality profiles of various cultures worldwide. Schaller and Murray (2008) theorized that in environments with a high risk of disease transmission, natural selection would favor alleles that are associated with lower levels of extraversion, openness, and sociosexuality. They found that cultures who experienced a historically high level of pathogen prevalence exhibited a personality profile characterized by lower levels of sociosexuality, extraversion, and openness to experience. In circumstances where pathogen risk is high, it is likely that selection favors a cautious personality type.

These studies suggest that personality traits are subject to selection pressures that vary across time and space, which is necessary (but not sufficient) for balancing selection via environmental heterogeneity to maintain heritable variation in the population. Both Camperio-Ciani et al. (2007) and Schaller and Murray (2008) describe between-group personality differences that are consistent with expectations from different selection pressures, but no strong inferences can be drawn. First, rather than the observed between-group differences being due to between-group genetic differences resulting from differential selection pressures, the group differences could instead be environmentally caused. There is no evidence to distinguish these possibilities. Second, even if the between-group differences are due to selection-driven genetic differences, this does not imply that within-group heritable individual variation (which is primarily what we are trying to explain) are also due to the same selective processes. Further, while the effect of environmental variation found in these studies may be statistically significant, it only accounts for a very small proportion of the total observed variance in personality.

As well as these limitations, mathematical modeling indicates that balancing selection via environmental heterogeneity can only maintain genetic variants at high frequency in the population – once a variant becomes rare, the balancing mechanism becomes unstable and the rare variant tends to be lost (Turelli and Barton, 2004). In contrast to this prediction, Verweij et al. (2012b) found that most of the genetic variation in personality traits is due to rare variants. As such, it is unlikely that balancing selection via environmental heterogeneity actively maintains much of the variation in personality traits. However, different selection pressures across time or space may still decrease the average strength of directional or stabilizing selection and hence slow the reduction of genetic variation by selection.

Sex-Dependent Selection

Sex-dependent selection occurs when the fitness of an allele depends on the sex of the individual it resides in. As with environmental heterogeneity, this means that there is no one optimum allele at a given locus, and selection can in theory act to maintain genetic variation. There are many examples of sex-dependent selection at the phenotypic level; that is, where certain characteristics or trait levels are more advantageous in one sex than the other (or advantageous in one sex and disadvantageous in the other). Physical examples are the most obvious – for example, height affects attractiveness and reproduction differently in men and women (Stearns et al., 2012; Stulp et al., 2013), and facial masculinity similarly has very different effects on men's and women's attractiveness (Lee et al., 2013; Mitchem et al., 2013). Twin studies have shown for height and masculinity that the same genes have the same effects in men and women; this creates a situation called intralocus sexual conflict, which can maintain genetic variation in the population because the same alleles have different fitness effects in males and females. While the tools exist to test for intralocus sexual conflict in psychological characteristics such as personality traits, little work has been done on this.

Frequency-Dependent Selection

Frequency-dependent selection occurs when the selection on an allele varies depending on frequency of that allele in the population. In negative frequency-dependent selection, selection favors an allele when it is rare, while more common variants are disfavored (Cockerham et al., 1972). The advantage of a rare characteristic relies upon exploiting an environmental niche with few competitors (Burger, 2005). As the characteristic becomes more common and competition increases, its advantage decreases. Frequency-dependent selection also applies to traits that allow individuals to occupy specific niches in the social environment, as well as the physical environment (Bergmuller and Taborsky, 2010). Negative frequency-dependent selection may be a viable mechanism for maintaining personality variation in humans, as it can theoretically maintain substantial amounts of genetic variation (Burger, 2005). Note that positive frequency-dependent selection cannot maintain variation because it disfavors rarer variations, speeding their elimination.

Heterozygote Advantage (Resulting from Antagonistic Pleiotropy)

Heterozygote advantage, or overdominance, can maintain genetic variation when the heterozygote (*Aa*) at a genetic locus has higher fitness than either homozygote (*AA* or *aa*) (Ewens and Thomson, 1970; Fisher, 1922; Hedrick, 2012). Heterozygote advantage can result from antagonistic pleiotropy, which occurs when a gene influences multiple traits such that one trait benefits fitness, while another trait is detrimental to fitness (Hedrick, 1999; Roff and Fairbairn, 2006). The best-known example of heterozygote advantage in nature is at the gene that causes sickle-cell anemia in humans. Individuals with an *AA* genotype are susceptible to malaria, while those with an *aa* type have an increased risk of mortality from sickle cell anemia. Those with the heterozygote genotype, *Aa*, however, do not develop anemia and are more likely to survive a malarial infection, which gives these individuals a significant fitness advantage (Hedrick, 2011). As the alleles, and not genotypes, are passed on to subsequent generations, variation can be maintained when the average fitness of each allele remains equal. The rarer an allele becomes in the population, the more likely it will become part of a heterozygote genotype, at which point its fitness, and eventually frequency, will increase. However, while this mechanism can demonstrably successfully maintain genetic variation (Ewens and Thomson, 1970), only a handful of genes with polymorphisms maintained by heterozygote advantage have ever been identified (Endler, 1986; Hedrick, 2012).

Summary

Overall, balancing selection seems an unlikely mechanism for maintaining genetic variation in personality. Balancing selection can only maintain genetic variation when highly restrictive conditions are met (Burger and Gimelfarb, 2002; Curtsinger et al., 1994; Hedrick, 1999; Turelli and Barton, 2004), and is often evolutionarily unstable (Curtsinger et al., 1994; Turelli and Barton, 2004). Mathematical modeling suggests that most forms of balancing selection – sex-dependent selection, frequency-dependent selection, and all forms of heterozygote advantage (including from antagonistic pleiotropy) – can only maintain variation in a few genes. Furthermore, all forms of balancing selection predict that genetic variation in personality should be due to common variants (Burger, 2000; Curtsinger et al., 1994; Hedrick, 1999; Kopp and Hermisson, 2006; Mani et al., 1990; Turelli and Barton, 2004).

In a study comparing the predictions of selective neutrality, balancing selection, and mutation–selection balance, Verweij et al. (2012b) found that the genetic architecture of personality traits is not consistent with the predictions of balancing selection. For example, the study showed that only a small proportion of the genetic variance in personality was accounted for by common additive variants, which is predicted by mutation–selection balance, but not by balancing selection (Verweij et al., 2012b). Verweij et al. (2010) also showed that personality is underlain by a very large number of genes of very small effects. Combined, these results are inconsistent with the predictions of any form of balancing selection. This conclusion is further reinforced by Bubb et al. (2006), who conducted a scan of the human genome to look for signals of balancing selection (regions of the genome with greater-than-chance densities of single nucleotide polymorphisms), and found no evidence for ancestral balancing selection beyond the few previously known examples. These various sources of evidence suggest that balancing selection is not a major cause of extant genetic variation in humans.

Mutation–Selection Balance

Under mutation–selection balance, genetic variation in a trait is maintained because the loss of variation from selection is offset by the accumulation of new mutations, so that selection and mutation exist in a state of equilibrium (Barton and Keightley, 2002; Zhang and Hill, 2005). Most mutations are at most mildly harmful to the fitness of an individual, and so are not immediately removed by selection. As a result, substantial amounts of genetic variation can potentially be maintained in mutation–selection balance (Gangestad, 2010). Keller and Miller (2006) argued that mutation–selection balance is the most likely mechanism of maintaining heritable mental disorders, which otherwise would be rapidly eliminated from the population due to their deleterious effects on fitness.

Selection will not usually eliminate new mutations immediately unless they are catastrophically deleterious (e.g., cause unviability or sterility). Because mildly deleterious mutations can accumulate over generations, each individual carries a load of mutations of variable number and severity. Alleles with large and/or dominant deleterious effects are rapidly eliminated, so deleterious alleles of small and recessive effects are more likely to be retained over many generations (Barton and Keightley, 2002). A mutation causing a 1% decrease in overall fitness will be carried by an average of around 100 individuals before being eliminated (Keller and Miller, 2006). Individuals pass on around half of their mutation load to their offspring, so those who exhibit a lower mutation load (perhaps indicated by traits such as physical attractiveness and intelligence) are more desirable as mates (Gangestad, 2010; Penke et al., 2007). Recent estimates indicate that new mutations in humans are introduced at a rate of 1.20×10^{-8} per nucleotide per generation (Kong et al., 2012). In the absence of selection or random drift the heritability of a trait would increase by approximately .1–1% each generation due to mutation (Barton and Keightley, 2002).

Zhang and Hill (2005) investigated whether mutation–selection balance could account for substantial heritable trait variation, in response to previous work which suggested that mutation–selection balance alone may not generate a sufficient amount of genetic variation to be a plausible mechanism of trait variation. Under mutation–selection balance, selection does not necessarily work in a directional fashion, but rather may favor the average phenotype over either extreme variation (i.e., stabilizing selection). Zhang and Hill (2005) analyzed a joint model of mutation–selection balance, where stabilizing selection was assessed in conjunction with 'apparent stabilizing selection,' in which mutations affecting a focal trait pleiotropically influence the fitness of other traits. Where previous studies had determined that neither mechanism alone was sufficient to sustain high levels of genetic variation, Zhang and Hill (2005) determined that their joint model of mutation–selection

balance could plausibly maintain genetic variation at high levels.

Using high-density genotype data and personality scores from thousands of individuals, Verweij et al. (2012b) directly compared mutation–selection balance, selective neutrality, and balancing selection as alternative explanations of personality trait variation. The study compared the genetic similarity of individuals to their personality similarity to determine how much of the variance in personality was accounted for by common causal variants. Verweij et al. (2012b) determined that common additive causal variant effects explained only a small proportion (~25%) of the genetic variation in personality, and that most of the genetic variation was due to rare variants and nonadditive genetic effects. From the genetic data, distant inbreeding could also be quantified for each individual, allowing detection of directional dominance of genetic effects. This analysis indicated that greater inbreeding was associated with the low-fitness ends of personality traits, suggesting that deleterious alleles were more likely to be recessive, which is a signature of mutation–selection balance. Combined, these results are consistent with a mutation–selection balance explanation of personality, but not with the explanations of selective neutrality or balancing selection (Verweij et al., 2012b).

Facultative Calibration

Consistent with the idea that personality variation has been maintained by mutation–selection balance is the suggestion by some researchers that an individual's personality trait levels have evolved to be calibrated to the level of other condition-dependent traits that are themselves under mutation–selection balance (Buss, 2008; Lukaszewski, 2013; Lukaszewski and Roney, 2011). For example, Lukaszewski and Roney (2011) proposed a 'facultative calibration' model of the personality trait extraversion: they propose that extraverted behavior is adaptive for attractive individuals (and strong individuals, in the case of males), but maladaptive for unattractive individuals (and weak males). Strong and/or attractive individuals may be better able to exploit the benefits of extraversion, such as social status or access to resources and mates, while minimizing the risks or costs, such as accidents, disease, and social conflict (Lukaszewski and Roney, 2011). Facultative calibration of extraversion therefore predicts that the optimum level of extraversion will vary between individuals, based on their other phenotypic qualities. According to this model, personality exhibits heritability because it is calibrated to variation in other condition-dependent heritable traits, a concept termed 'reactive heritability' (Tooby and Cosmides, 1990). Lukaszewski and Roney (2011) found that higher levels of extraversion were correlated with higher levels of strength and attractiveness, consistent with a facultative calibration model. Lukaszewski (2013) recently expanded the idea to other personality traits and a central construct to which these personality traits were calibrated: 'relative bargaining power.' Again, correlational evidence was largely consistent with the facultative calibration hypothesis.

Although examining phenotypic correlations is an important first step in testing the facultative calibration hypothesis, genetically informative studies are required to properly test these ideas. Findings from identical and nonidentical twins (Haysom et al., Manuscript submitted for publication) cast doubt on key aspects of the facultative calibration hypothesis: Most notably, only a very small proportion of the heritability of extraversion can be accounted for by physical attractiveness and other traits related to relative bargaining power.

Conclusions

While there has been substantial theoretical exploration of the possible mechanisms underlying heritable personality variation, there is a strong need for more empirical research. The empirical research that does exist suggests that selection pressures vary across time and space (Camperio-Ciani et al., 2007; Dingemanse et al., 2004; Schaller and Murray, 2008), but there is no direct evidence that this spatiotemporal heterogeneity actively contributes to maintaining heritable variation within populations. Indeed, genetic evidence is inconsistent with the genetic architecture that would be expected if selection were actively maintaining variation in personality traits (Bubb et al., 2006; Verweij et al., 2012b). In contrast, genetic evidence is consistent with predictions from mutation–selection balance, where the multigenerational accumulation of random, mildly deleterious mutations is offset by selection against those mutations (Verweij et al., 2012b). Further theoretical and empirical work is needed to understand how random mutational variation manifests in a dimensional personality structure, and how dimensions of individual differences are related to species- or sex-typical behavioral adaptations (see Zietsch, 2009: pp. 85–99).

Personality: Historical and Conceptual Perspectives

Abstract

This article traces the 24-century evolution of embryonic concepts of personality psychology into a fully effloresced scientific, contemporary domain. This analysis links the rise of Western individualism to the empirical study of differences in temperament and personality. Focus is placed on the biological, empirical substrate of personality development sketched in Hellenic science, the negative psychology of early Middle East and European religious movements in the West, and their gradual mutation into the positive psychology of a secular, evidence-based personality and developmental psychology.

Defining Personality

The concepts that are useful today in advancing personality psychology have evolved over thousands of years. In the West, psychology in all its guises was long subsumed under the rubric 'philosophy.' This rubrical issue does not invalidate the idea that the study of personality had been sluggishly maturing over millennia before it effloresced in the nineteenth century as a formal science. The term personality is now typically used to label consistent behavioral, cognitive, and emotional reaction patterns that individuals experience and predictably exhibit. In this context one can take it as axiomatic that even a spontaneous thought is a stimulus to one's brain and internal milieu. Further, it is assumed that categorical terms such as 'personality,' 'traits,' 'factors,' or even, say, 'species,' are mental constructs; they do not exist independently in nature, though they do have a foundation in reality. Thus one can only be said to actually possess a personality in the sense that one is assessed by others and viewed by oneself as disposed to behave consistently and predictably in a variety of situations.

Given the complexity of human beings and the data-dense web of relationships in which they promote their well-being as they perceive it, personality psychology was progressively split into numerous specialties, for example, trait psychology, self psychology, emotion psychology, gendered personality, motivational psychology, disordered personality, neuroethology, cultural psychiatry, and many others. Given the scope of personality psychology as a field of study, one finds, not surprisingly, that it implicates many disciplines beyond psychology – some broad-scale such as anthropology, sociology, evolutionary biology, ethology, and neuroscience. Others, such as cognitive neuropsychology or social role theory, are narrower in scope, though intrinsically complex in themselves.

Conversely, as Moghaddam (1998), a social psychologist, and Pinker (2002), a cognitive psychologist, have cogently explained, there are hundreds of specific behavior patterns (and schemas for calibrating and valuing relationships) that are universal, that is, common to the human species. (Linguists and cultural anthropologists have developed the notions of *emic* and *etic*, neologisms that are highly useful to designate culture-specific and cross-cultural traits, respectively. Psychologists have borrowed the terms to designate analogous concepts in their respective disciplines.) Even more broadly, certain personality theories have been useful in comparative psychology, exploring the characters, say, of canines, bulls, octopi, rats, (For example, Jaak Panksepp and Jeff Burgdorf authored 'Laughing' rats and the evolutionary antecedents of human joy? *Physiology & Behavior*, 79 (2003) 533–547.) or even microbes, ("Motile microorganisms of the same species are like solitary eccentrics in their swimming behavior. When they are searching for food, some tumble in one direction for precisely so many seconds before quitting, while others tumble differently and for different, but characteristic, periods of time. If you watch them closely…you can tell them from each other by the way they twirl, as accurately as though they had different names" (Thomas, 1979: 2).) and their interrelationships with humans as well as among themselves.

In this perspective, the term personality designates not only the distinctive social and behavioral differences we observe between individuals, but also distinctive cultural patterns among nations – and, indeed, some behavioral norms that are found in all societies. Thus personality can be construed as a multidimensional, continuous variable stretching between molar and molecular poles, from patterns of personal behavior that are characteristic of the human species (see Brown, D.E., 1991) to those of a single human being. Near the molar pole this evokes etic, anthropological schemas; toward the molecular pole emic, personological ones.

Principles and Disciplines

Early Biological Substrates of Personality

Hippocrates (born *c*.460 BC) was late pre-Socratic in inspiration. He understood that "from nothing else but the brain come joys, delights, laughter and sports, and sorrows, griefs, despondency, and lamentations" (1992: 336) – not to mention madness, immobilizing anxieties, and delirium. He deplored attributing mental illnesses to divine causes and averred that we must seek answers in natural causes – and remedies in human resources. Plato noted in *Timaeus* (86e ff: 474) that humans' varying physiological conditions can cause turmoil and disease in their spirits. He endorsed the Hippocratean notion that bodily humors (blood, phlegm, yellow bile, and black bile) influence population variability of temperaments. The legacy of this archaic but useful formulation of personality traits (sanguine, choleric, phlegmatic, melancholic) will be evident to students of Carl Gustav Jung (and of the 'Myers–Briggs Type Indicator,' a popular

assessment instrument that is a derivative of Jungian personality theory). This Hippocratean schema conforms roughly to Hans Eysenck's four-factor model of trait psychology (alternatively compacted into a three-factor model). Although analogous Chinese and Indian schemas can be cited here, their impact on contemporary personality psychology is not as clear or immediate.

Personality in Later Hellenism

Many other concepts that are useful today in exploring the science of personality psychology can be traced back to the Hellenic era. For example, the Aristotelian principle that the mind is, as it were, a blank slate destined to be written upon was reinvented in the later Renaissance and has since been extensively modified in the modern sciences of developmental psychogenetics. Notable contributions were made by Plato and Aristotle, the 'twin stars' of Hellenic thought as Arthur Koestler called these philosophers.

Among countless personological examples, one can cite Plato's (370 BCE/1991) observations about the character of young boys. In *Laws* he wrote: "Now of all wild young things a boy is the most difficult to handle. Just because he more than any other has a fount of intelligence in him that has not yet run 'clear', he is the craftiest, most mischievous, and most unruly of brutes. So the creature has to be held in check, as we may say, by more than one bridle" (Book 7, Section 808d). Yet Plato cautions that the privacy of the home itself conceals (presumably abusive) familial reactions to children's passions and outbursts that can bring on 'a medley of incongruities' into their characters. This and numerous other astute observations can be endorsed by all contemporary developmental psychologists.

Plato insisted there should be compulsory schooling for all, both males and females, as the care, instruction, and nurturance of all children will shape their adult character. Tilting against a prevalent misogynism, to which he was not totally immune, he asked, what can be more absurd than depriving women the opportunity to follow the "same pursuits [as men] with all their strength and with one mind" – and here note the economic kicker – "for thus the state, instead of being a whole is reduced to a half, but has the same imposts to pay and the same toils to undergo" (Plato, Laws. *c*.350 BCE/1997, [804]: 1473). He noted moreover "We are not all alike; there are diversities of natures among us which are adapted to different occupations" (Plato, 4th *c*.BCE/1952a. *The Republic* Book II, Section 370: 317). Here we have not only a precursor to the career psychology principle, 'aptitude–occupation fit,' but a salient recognition of individual differences. Aristotle provided equally cogent views on individual differences and on the influence of learning and social forces that shape personality. Attention to personality types can be found in his *Rhetoric* and his *Ethics*. His student Theophrastus (*c*.4th *c*.BCE/1929), many of whose writings have disappeared, left arresting portraits of certain personality types.

Augustine in the Ascendant

Gnostic beliefs of numerous religious sects, freighted with mystic conceptions of the world and negative views of human nature, contested the brilliant science of the Pythagoreans and later Hellenes (see Jonas, 1958; Robinson, 1977). Certain elements of Gnostic belief systems infiltrated early Judaic traditions and a nascent Christianity, and powerfully shaped the evolution of the concept of the Human in the first millennium CE. Though there were many varieties of these Gnostic sects, traceable to Persian and other Middle Eastern cultures that preceded Roman hegemony, they all shared beliefs in domains of light and dark, truth and falsehood, spirituality and materiality, good and evil supernatural agents, and, in some sects, the radically flawed nature of 'Man.' (Scholars note that certain sects declaimed that "the very origin of the world was attribut[able] to a terrible fault" (e.g., Robinson, 1977: 4) and that Evil, destined to rule, was abundantly evident in secular societies. In sharp contrast to this mystical ethos Plato, in *Timaeus* (4th *c*.BCE/1952b, [86, 87]), affirmed the contrary that humans are not voluntarily bad but become bad by virtue of physiological disorders and a bad education. Further, these entail psychological disorders that in varying degrees of intensity are aggravated by evil discourse uttered in public or private; and by evil government, which can worsen the character of the state's citizens (474).) These dualistic systems shaped several streams of thought bearing on the nature of the Human. In the West they dominated up to the Renaissance – and in attenuated form even into the nineteenth century when they spawned pathognomonic schemas of human nature.

The seepage of select eremitical and gnostic ideas and values into the Christian systems that mushroomed during the first millennium (CE) had a stultifying impact on the pursuit of Hellenic science. The most potent influence was St Augustine's, whose conversion to Christianity from Manicheism allowed the infusion of a quasignostic ethos, no doubt indeliberately, into the structure of what had become Christian orthodoxy. Those attitudes were enmeshed with a prevalent Neoplatonism, which, while admitting the goodness of the material world, nevertheless denigrated humans' carnal nature. Augustine's ascetic counsels may seem egregious to readers of our times, yet they were prevalent in the anguished and despair-ridden epoch that ushered in the European Dark Ages. ("To escape temporal encapsulation in the present, hermeneuticists have provided exegetes and historians with a scientific methodology for understanding the thinking of individuals who were immersed in a historical and cultural context different from their own. Initially developed to interpret Sacred Scripture, hermeneutics protects scholars from anachronistic perspectives and is no less important for historical texts bearing on psychology" (Dumont, 2010: 1–2).)

No doubt the antitheses of theocentric asceticism and geocentric science played out to the detriment of the latter. Archimedes' *The Sand Reckoner*, which investigated out of sheer curiosity the number of grains of sand that it would take to literally fill the universe, must have stupefied Augustine in his mature years – committed as he was to exploring exclusively the mysteries of the supernatural and to approaching the Divine Object of his devotion. Indeed, he considered studying the course of the stars and other phenomena of the natural world as morbid vanity. Such an important personality trait as curiosity was in his estimation, an illness. This view prevailed for centuries.

Augustine's views on other human proclivities would have a profound influence on personological approaches to daily life in the Dark Ages that followed upon the decline of the Roman Empire. He viewed our senses as bridges to seductive worldly pleasures (Book X, Chapters 31–35 of *The Confessions*). He deplored the enjoyment of ecclesiastical music unless attention was given more to the meaning of the words than the beauty of the sound. Comparing 'enjoyment' to 'attention' raises a scaling problem he did not address. Bach's *Matthew Passion* or Handel's *Messiah* would have presented him with challenging temptations. He extolled the value of fasting and deplored taking pleasure in eating even when famished – indeed he regarded food and drink only as medicine to repair the wastage of the body (*The Confessions*: 103). A twenty-first-century psychologist would demur. The delights taken in a family dinner tastefully prepared by its members is a bonding process for the entire family. Enjoying our food and drink is no more separable from the conviviality of a shared meal than is separating the butter from the batter.

The Dark Ages

The centers of learning in the Dark Ages were dedicated more to religious than philosophical pursuits – though they were somewhat intermeshed. The monasteries were the epiphenomena of a mushrooming Christianity more than academies to engage in Greek and Roman intellectual pursuits. Although the works of Lucretius, Marcus Aurelius, Plutarch, and Cicero, among others, were studied by individual scholars, the copying of religious manuscripts and the evangelization of the local populace were of greater importance to monastics. The cognitive structures of the peasantry, no less than monastic communities, were suffused with the ideals of the Church Fathers, most notably Jerome, Augustine, and Gregory the Great. Even rulers like Charlemagne took inspiration from principles from Augustine's *City of God*. There is little evidence this emperor read philosophy and the work of the Neoplatonists.

Five centuries elapsed between the Augustinian *oeuvre* and the appearance of an equally great thinker, the brilliant John Scotus Eriugena, who revived a dormant Neoplatonism, and seven centuries before Moses Maimonides, the Spanish-born Judaic, Arabist, Hellenist polymath, appeared. In the earlier interval only Boethius, a sixth-century politician of uncertain religious beliefs and author of the *Consolations of Philosophy* (and other philosophical works) illuminated the post-Patristic period. Little information survives suggesting people were viewed as distinctly individualized. Our modern concept of an individual who is documented as such with a birth certificate and later a social insurance number, endowed perhaps with a medical record, a coded driver's license, a Medicare card, and a (typically) inalienable passport would have struck the denizens of Europe in the Dark Ages as preposterous. Individuals are now concerned that their identity can be stolen – and that they can be impersonated in a way that diminishes their rights, status, and property. Though impersonations no doubt happened, there is little evidence that such even entered the theater of, say, a serf's waking state. The emergence of a post-classicist individualism and the notion of individual differences lay in the future.

The Sluggish Rise of Individualism

In our modern developed world each of us normally finds a space that affords us solitude. In the first millennium, life was predominantly communal. Private bedrooms and baths were not the norm nor are they today in many parts of the world; neither were looking glasses in plentiful supply, to aid in personal self-grooming. The individual was less a person than an idea as Philippe Ariès (1962) suggests. Neoplatonic essentialism dominated the existentialism that was later to appear in the music, poetry, and theater of popular entertainment. Portraiture in the later Middle Ages depicts members of a family of varying ages in such wise that they are hardly distinguishable, except by size and sex. One cannot of course imagine individualism without evoking the very differences that distinguish individuals from each other. In a later humanist era the depiction of individuals with unique needs, aspirations, values, and habits would inevitably give rise to concepts of personality.

These views would only gain momentum in the second millennium. Slowly people began to appear as free actors, each distinct from everyone else, with unique physical and characterological features. Artisans, a merchant class, educators, poets, and dramatists progressively began to see themselves and others, not as Platonic knock-offs from a universal template, but as differentiated and unreplicable individuals – embodying a personal history, particular tastes, occupational aptitudes, evolving capabilities – displaying and enjoying a panoply of virtues and faults. The extent to which an evolving ethos and economic order generated the concept of individuality (and vice versa) is not yet known. Fully understanding what generated the nascent individualism of the Middle Ages that served as the seedbed for a renewed concept of personality is still an object of study.

Passions and the Individual in Love

People had been regarded in the Dark Ages as copies struck from a broken mold, 'conceived in sin,' 'shapen in iniquity,' and burdened with the legacy of Original Sin. Taking any pleasure in sexual experiences was regarded as intrinsically sinful (but only venially so within the framework of marriage, according to Pope Gregory I (Finn, 2011: 51)). Consistent with this notion, the celibacy of Jesus of Nazareth and the Virgin Mary was lofted to a Christian's preferred state of life. In the wake of the moral tsunami unleashed by Augustine, the cult of the Virgin flourished. That ethos dominated Europe for eight centuries, which pulled in tow the Carolingian dynasty, suffused European societies with a penitential mindfulness, and filled the cultural landscape with magnificent architectural and artistic testaments to the Virgin's virtues and intercessory power. In twelfth-century Europe, the iridescent love affair between a renowned theologian, Peter Abelard who was in holy orders, and his talented paramour, Héloïse Garlande (who in due course became pregnant) erupted in disgrace, genital mutilation, and tragedy. The epic proportions of this flagrant yet beautiful love story attest to the scandal it generated in the hoi polloi, the power élite and crown, and to some extent the clergy.

The Minstrelsy of Medieval Europe

The drama of Peter and Héloïse was a prequel to twelfth century minstrelsy, comprising Provençal troubadours, German-language *Minnesinger*s, French *chansonniers*, and other professional performers who traveled widely and enchanted their audiences with epic as well as mundane accounts of romantic love, resonances of which can be found in Orff's Carmina Burana – musical renditions of racy Medieval poems. Falling in love – what St Augustine deplored as a satanic snare to which he succumbed – was celebrated in the *canzoni* and epic poems that were composed and sung by these minstrels. These were arguably a powerful dynamic in shaping the individualism of that time. Two people who fall passionately in love find each other highly individualized to say the least. Lovers who only have eyes for one another do not regard their partners as fungible love objects.

Personality in Renaissance Literature

As the culture of courtly and romantic musical performances gained popularity and acceptance in Europe, the appreciation of individual differences increased – with lovers singing 'ballads to their mistresses' eyebrow.' The works of Dante, Petrarch, Boccaccio, and Chaucer, among others, depict the subtle as well as salient personality traits of both eminent and ordinary folk. Chaucer's *The Canterbury Tales* display fine characterizations of pilgrims as well as haunting descriptions of their paramours and family members. The richly embroidered personalities of the miller, the prioress, the physician, the merchant, the oft-widowed wife of Bath – are described with humor, subtlety, and fine detail by Chaucer. These are brilliantly illumined characters that enchant us to this day. One can view the intrinsic logic of the society of the day that brazenly overreached the religious constraints of earlier centuries – and then permitted amends of sorts to be made. The cook, for example, describes

> A prentice living in our town
> Worked in the victualing trade, and he was brown,
> Brown as a berry: spruce and short he stood,
> As gallant as a goldfinch in the wood.
> Black were his locks and combed with fetching skill;
> He danced so merrily, with such a will,
> That he was known as Revelling Peterkin.
> He was as full of love, as full of sin
> As hives are full of honey, and as sweet.
> Lucky the wench that Peter chanced to meet.
> At every wedding he would sing and hop,
> And he preferred the tavern to the shop.
>
> p. 324

The tide of humanism had begun to rise with these creative and daring thinkers and is epitomized in the works of William Shakespeare. He held up a mirror to the human throngs that have through the ages attended and studied his plays. Like lay psychologists, we have caught glimpses of ourselves, our strengths, foibles, aspirations, joys, terrors, depressions, and tragic flaws. The 'vasty deep' of the Bard's mind reflected the complexities of the human race in diverse roles and connected us to our most deeply sourced feelings. In his plays he limned the personalities of over 120 characters – among the most notable, Falstaff, Prince Hal, King Lear, Cordelia, Iago, Rosalind, Lady Macbeth, and that crazed depressive, Hamlet – the study of whom continues to reward the personality theorist. This genius not only gave us a language for describing human personality, but also sketched beautifully the crises and stages of a human's life.

Shakespeare is the peerless example of a class of dramatists, portraitists, essayists, novelists, sculptors, and painters that emerged in that humanist era (see Dumont, 2010). Among the greatest were Cervantes, who is numbered among the novelists of the Western canon, and Michel Eyquem de Montaigne (1533–92) an essayist who likely (but unknowingly) spirited some insights into the plays and sonnets of his contemporary, Shakespeare.

Approaches to Contemporary Personology

Stages of Human Development

Personality psychology is founded more on a sound developmental psychology than on any other psychological discipline. Science, as such, is a vast interlocking system in which ideas get sifted from one discipline to another. The attitudes and values that shape them individually have implications for all the others. An example is evolutionary psychology, which reverse engineers human nature, such as we understand it and, abetted by a fossil record, infers the conditions and causes that brought about our current condition, thus suggesting new developmental hypotheses. That there are stages in personality development of a lawful and etic character has always been evident, as has the knowledge that all humans play many parts during the course of their life. A classic literary example of developmental stage theory is Jaques' soliloquy in Shakespeare's *As You Like It*.

> All the world's a stage,
> And all the men and women merely players:
> They have their exits and their entrances;
> And one man in his time plays many parts,
> His acts being seven ages. At first the infant,
> Mewling and puking in the nurse's arms.
> And then the whining school-boy, with his satchel
> And shining morning face, creeping like snail
> Unwillingly to school. And then the lover,
> Sighing like furnace, with a woeful ballad
> Made to his mistress' eyebrow. Then a soldier,
> Full of strange oaths and bearded like the pard,
> Jealous in honor, sudden and quick in quarrel,
> Seeking the bubble reputation
> Even in the cannon's mouth. And then the justice,
> In fair round belly with good capon lined,
> With eyes severe and beard of formal cut,
> Full of wise saws and modern instances;
> And so he plays his part. The sixth age shifts
> Into the lean and slipper'd pantaloon,
> With spectacles on nose and pouch on side,
> His youthful hose, well saved, a world too wide
> For his shrunk shank; and his big manly voice,
> Turning again toward childish treble, pipes
> And whistles in his sound. Last scene of all,
> That ends this strange eventful history,
> In second childishness and mere oblivion,
> Sans teeth, sans eyes, sans taste, sans everything.
>
> Act II, Scene vii.

Three centuries later, the principle of 'multiple personas' was luminously described again by William James (1890/1990: 189–190).

Developmental concepts emerged in abundance in the works of Montaigne, Francis Bacon, Hobbes, Locke, and other observers of the human scene. Newtonian and Leibnizian science shaped the European mind. The loom of history, on which the lives of individuals and their societies are spun like so many endless tapestries, began to depict a materialist and mechanist vision of humans in the seventeenth and eighteenth centuries. People were imagined as (Pierre-Simon) Laplacian puppets driven by causes, noble and ignoble, over which they had no control (cf Menand, 2001: 177–200).

Group as well as individual differences were amply described in the literature of the classicist and Renaissance eras of the West. Divergences of manners, temperaments, and fashionable illnesses were evidenced not only among individuals in cross-sections of societies, but also longitudinally in societies and subcultures over generations. Some patterns remained constant, an example of which is seventeenth-century aggressiveness. Philippe Ariès, for example, noted that in 1588 the king of France sent magistrates, police superintendents, and some sergeants-at-arms to disarm students who during the St Germain fair in Paris "had gone there armed to behave insolently." In 1680 at the Collège de Bourgogne a regulation was enacted: "Neither firearms nor swords are to be retained in pupils' rooms and those who possess such weapons must hand them over to the Principal." In Jesuit colleges students, upon entering, were in return for a receipt relieved of their weapons; their arms were placed in the custody of the Master. 'Jealous in honor, sudden and quick in quarrel' youths and men-at-arms were quick to engage in dueling and other forms of combat. These deadly encounters, endemic to Europe and England (Ariès, 1962: 315–328), eventually gave way to fist fights and wrestling matches.

The manners and mores of Western societies changed gradually, almost imperceptibly, in premodern Europe compared to changes in our rapidly evolving contemporary times. In the post-Cartesian age that ushered in brilliant scientific and technological achievements, Platonic/Cartesian dualism began to suffer continuous attacks from theistic, deistic, and atheistic currents of thought. Intellectual revolutions like Keplerian and Newtonian science spread with alacrity among the cognoscenti. The Enlightenment, spawned by eighteenth-century thinkers, became an intellectual flood tide against which established religions have to this day fought a rearguard action. A cleavage opened between 'believers' and secularists, idealists and empiricists, traditionalists and laboratory-bench methodologists. The scientific *Zeitgeist* seeped into the nooks and crannies of the academies and the markets – by stealth as it were. Urbanized Europeans, simply by 'breathing the common air,' experienced a transmutation of mores that psychologists could not evade. The mathematicization of cognition on which Johann Friedrich Herbart labored in the late-1700s began a process that would adumbrate into the twentieth century, when Allport and Odbert catalyzed the search for underlying personality factors and Raymond B. Cattell helped refine factor analysis, the privileged instrument for the advancement of trait psychology.

Personality Theories and Nineteenth-Century Science

Although personality psychology was not yet regarded in the nineteenth century as a formal discipline (nor was any psychology), there were several streams of scientific investigation that effectively generated models for it. Building on the science of such thinkers as Gottfried Wilhelm Leibniz (1646–1716) and Johann Friedrich Herbart (1776–1841) who did seminal work on human cognition, experimentalists Gustav T. Fechner and Hermann von Helmholtz, among others, conducted research on the neurophysics of human motivation. Helmholtz, indeed, discovered in 1861 the dynamic of unconscious inference. He regarded this "as a kind of instantaneous and unconscious reconstruction of what our past [had] taught us" (Ellenberger, 1970: 313). The implications of this for personality psychology are profound as it indicates how adaptive behaviors in novel situations can intuitively and instantaneously surface.

We fabricate memories to explain our behavior when we cannot otherwise plausibly explain it to ourselves or others. By using posthypnotic suggestion, Jean-Martin Charcot, a renowned neurologist at the Salpétrière (Hospital) in Paris, demonstrated that we tell more than we can know. And Nietzsche, who unmasked many defense mechanisms we use to rationalize our behaviors, wrote that when consciously speaking we produce "a more or less fantastic commentary on an unconscious perhaps unknowable, but felt text" (cited in Ellenberger, 1970: 273) – lying to ourselves even more than we do to each other. The implication is that unconscious schemas, often ancient and inaccessible, direct our current conscious behaviors – and the ideational traffic goes in both directions. Thus, the constituents of our personality reside on both sides of a fuzzy liminal divide.

Arthur Schopenhauer and Natürpsychologie

Schopenhauer (1819) generated one of the dominant motifs of nineteenth-century psychology in *The World as Will and Idea*, a masterpiece of the Western canon. As Henri Ellenberger noted, he presented a view of humans that was pansexual, pessimistic, irrationalist, and determinist. Like Nietzsche whom he influenced, his ideas on the role of tacit cognitions in human behavior set the epistemological stage for psychodynamicists of a later age. His influence was pervasive. Thomas Mann (a Nobel laureate in literature) observed that Schopenhauer's views can be mapped on the Freudian personological schemas that adumbrated into the twentieth century.

Romantics in the Natürpsychologie tradition in which Schopenhauer was embedded placed great emphasis on beauty, virtues of the Volk, nature, homeland, the life of the mind, sentiments of affection, the spiritual, and related values that were vectored by poetry, music, belles-lettres, and a bucolic life style. Goethe and Schiller were venerated pillars of this tradition that served as counterpoise to the rationalism of the Enlightenment *philosophes*. Tension arose of course with the natural scientists, which was finessed by Gustav Fechner, a psychophysicist, experimental estheticist, and philosopher, and other scientists who shared both traditions. Fechner frequently conducted studies of a philosophical character, and Wilhelm Wundt did extensive research in historical, folk

psychology (Völkerpsychologie). The struggle to define personality psychology eventually tilted in the first third of the twentieth century in favor of the psychiatrists and clinician researchers.

Clinician Researchers

The most influential personality theorists in the nineteenth century were medically trained psychotherapists. Their clinical discoveries made during a professional lifetime spent treating, in large part, upper-class female patients as well as others within the context of asylums and mental hospitals, inevitably influenced their modeling of 'normal' human beings. A pathognomonic bias was structured into their theories of personality development and conceptions of the Human. Although they studied with many great 'brain scientists' and neuropathologists such as Ernst Wilhelm von Brücke and Theodor Meynert, or neurologists such as Jean-Martin Charcot, they abandoned the nerve sciences and ensconced themselves in their offices and hospitals to conduct talk and behavioral therapy. The reason, as Emil Kraepelin observed at the turn of the century, was that the meticulous work of the lab-based neuroanatomists had given the world precious little insight into methods for healing mental disorders. Théodore Flournoy, Auguste Forel, Eugen Bleuler, Paul Dubois, Sigmund Freud, Pierre Janet, and Carl Gustav Jung, among many others, predominantly explored the world of psychodynamics. Alfred Adler, a promoter of a community-based, positive psychology (and the ideology of community interest – *Gemeinschaftsgefühl*) was a notable exception (see Henri Ellenberger, 1970, for a peerless historical analysis of nineteenth-century psychiatry, and Shorter, 1997; for a more concise review).

Psychoanalysis

The most salient of the theories of personality that emerged from late-nineteenth-century psychiatry was developed by Sigmund Freud. It began in earnest by the publication with Josef Breuer of *Studies on Hysteria* in 1895 and continued to evolve into Freud's advanced years. The archaic developmental psychology on which Freud built his psychosexual stage theory had become seriously outdated by mid-twentieth century. Radical revisions of his male-centered perspectives were necessitated by an evolving sociopolitical climate and advances in various human sciences. There was a vigorous push-back by liberal, women's movements, keynoted most notably in the works of Karen Horney.

Critical to the Freudian paradigm is the hypothesis that human development is shaped by the drama of son and father in a (the so-called Oedipal) conflict for the affections of the central female figure in their lives. The incestuous overtones in this rivalry, purported to be universal, raised serious anthropological difficulties. That a male child normally has an incestuous appetition for his mother has not been demonstrated. (Freud acknowledged that his theories were not evidence based. Indeed, in recounting the case of 'Little Hans' he stated he had never met a patient who willingly admitted to have ever experienced castration anxiety, a concept integral to the Oedipal conflict.) Indeed the *Westermarck Effect* implies the contrary: that those who are raised in close familial relationship with each other are typically averse to sexual partnering. If the Freudian vision of an Oedipal conflict is true, it raises a serious issue for females. As the development of a moral sense depends on the resolution of the Oedipal conflict in a univocal sense, the development of a 'superego' is compromised among women. This is nettlesome to those who, like Carl Jung, take it as axiomatic that women's moral development is at least on a par with men's. Jung attempted to defuse the problem for Freudian psychodynamicists by inventing the Electra complex – a ploy that Freud always rejected. Following World War I, Freud added the earlier Adlerian aggressive drive to the sexual. He also formally supplemented his psychosexual stage theory with a topographical model positing the hypothetical constructs, id, ego, and superego.

This psychiatric phase in an evolving personality psychology was redirected by the science of developmental psychology and other related social and behavioral sciences.

From Illness Models to Wellness Models of Human Nature

The pathognomonic theories of personality that proliferated in nineteenth-century psychiatry began to yield to powerful currents of positive psychology following World War I. The modern origins of wellness models of human nature are arguably anchored in the work of Wertheimer, Koffka, and Köhler, a team that developed Gestalt psychology – and provided a rich perspective on the individuality of each person. An influential book *Holism and Evolution*, written by Jan Christiaan Smuts, a South African naturalist, soldier, politician, and philosopher, appeared in 1926 and enriched this perspective. Positive psychology was given further impetus by Alfred Adler's educational reforms and his principle that mental health depended in large part on living in sanitized communities. A former member of Freud's Wednesday Psychoanalytic Society from which he was dismissed, Adler is often mistakenly thought by the popular press to have been a Freudian. Teleologist and contrarian that he was, he averred that probing a patient's personal history was less important than planning his or her future. He rejected the pessimism, pansexualism, and determinism of Freud, affirming that humans have only one drive: self-actualization.

The groundswell of positive psychology that was launched by these pioneers and advanced by Henry Murray, B.F. Skinner (an eminent behaviorist), Gordon Allport (among the first factor analysts), Abraham Maslow, Carl Rogers, and many others, is now being furthered by such notables as Martin Seligman and Mihaly Csikszentmihalyi.

Select Positive Developments

Personality psychology is so complex that it is not possible to examine all aspects in a single text or handbook, impressive as the depth of coverage may be. Health enhancing self-grooming, playfulness, attitudes to food and cooking, altruism, curiosity, sense of humor, dignity, empathy, ticklishness, creativity, self-transcendence, fairness, and intercorrelations of many such facets will long be research domains for personologists. Many

are still given short shrift in graduate-level textbooks. This complexity is multiplied when one stirs in multicultural variables (e.g., see Marsella et al., 2000). Over the past century several others of a life span and gerontological character have been klieg-lighted.

Reduction of Pre- and Postnatal Stressors

Innumerable prenatal stressors (not least, say, maternal adrenocortical stress hormones and other fetus-toxic substances) and early childhood traumatic experiences have now been shown to seriously affect for the worse the normal development of personality (as Mary Ainsworth and John Bowlby, among many others, during the past 75 years have shown). The nurturant bond of an infant with its primary caregivers is ruptured by long hospitalization, divorce, parental death, or other traumatizing experiences. As with severe stimulus deprivation (both social and material) those events can result in enduring harm. Though complex and multidimensional, later positive experiences and healthful environments can mitigate their effects as Michael Rutter, Jerome Kagan, Robert Plomin, and other recent developmentalists have demonstrated. As Arnold Gesell noted, reducing childhood stress by scheduling educational experiences to fit actual rather than anticipated levels of neurological development is of cardinal importance.

Epigenetics

The strength and duration of environmental variables and their interaction with one's genome produces, for better or for worse, far-reaching effects that are possibly transgenerational. Much of the plasticity in our neuroemotional systems depends on epigenetic effects, that is, the expression of dormant genes (which can be positive or negative) triggered by significant environmental events. Positive experiences can do much to repair developmental damage and effect healthful neuronal alterations. Indeed, Nobelist Eric Kandel intimates that personality change through psychotherapy is achieved through gene expression at the neuronal level. Such findings strengthen the foundations for furthering positive psychology, which could hardly have been imagined by the grand-system builders of the late-nineteenth century.

Neoteny

In the context of positive personality development, the principle of neoteny comes into focus. Humans have a comparatively lengthy childhood. Neoteny affirms that the evolutionary prolongation of juvenile stages into adulthood has favored increased neural plasticity, rich behavioral opportunities permitting optimal life-altering choices, and the partial if not total reversal of the effects of destructive childhood experiences. Neoteny allows for the remediation of serious mistakes and provides affordances of redemption for adolescents or their caregivers. The developmental advantage of this is that as children become neurologically more mature, they can better compute the risks and the unforeseen consequences to themselves and others that their immature behaviors can generate. And they can avail themselves of future benefits in behavioral repertoires that are more prosocial – as well as career options that are more beneficial for them. A collateral benefit arises in that the neurological maturity of malefactors and their level of intelligence (fluid as well as crystallized), have a bearing on legal judgments of their guilt. This is a significant educational, developmental, and personological issue.

Overturning Homuncularism

Homuncularism is a multifaceted, now outdated construct positing that an infant is an integrally preformed human being whose infantile impulses and reaction potentials are the same as an adult's. The infant male is thus regarded as a 'little man' who can enter into the same dramatic sexual struggles – incestuous, hetero/homosexual, polygynous (and variants of these), which his father and other adults engage in. That allowed personologists to hypothesize theories of personality development that range from the most rigidly preformationist to the modestly predeterminist. Ausubel et al. (1980) affirmed that a modern example of homuncularism is the classic psychoanalytic notion "that infantile and adult sexuality are qualitatively equivalent" (15).

A mitigated variant of preformationism is predeterminism. Arnold Gesell, for example, a renowned developmentalist posited that we are biologically programmed, such that our temperamental traits as well as more specific manners are instinctive. Studies of twins separated at birth have given some support to a current genomic view. In a greatly attenuated form, the predeterminist position is mainstream science today. Though environmentally accommodative, this view accounts for as much as 60% or more of trait variance in the Eysenck, Five-Factor, or Cattellian models of personality types. On the other hand, the advice of neuroscientist Joseph LeDoux (2002) relative to the influence of the human genome on our personality seems apt. He acknowledges that our human nature is relatively constant, but he notes that we are not born preassembled. In our individual lifetimes we can only be 'glued together by life.'

Summary

The history of psychological sciences does not have a beginning, middle, and end, or an Aristotelian *telos* that drives it – unless one transmutes it into a theology. This is particularly true of the science of personality. Michael Mahoney (1991) similarly averred that history cannot be construed as proceeding toward a particular end-state. Using a fiction writer's techniques to narrativize the sweep of human history risks imposing cognitive schemas and plot lines on a panorama that has no logic or terminal climacteric, except in the historian's mind. One cannot in short, impose a teleological, still less gnostic, directionality that suggests there is a covert plot or story line to be uncovered.

In the light of current science, it appears that theories of personality will continue to evolve in directions that are genetics-based yet less instinct-driven, life-span developmental, holistic and sociobiology based, gender-equal yet gender-differentiated, cross-culturally conditioned, and Heraclitean, that is, fashioned by the changing societies and multiple cultures in which one is bred and educated. Clearly, personality

theories that predate the Second World War are not, by and large, consistent with these descriptors. It appears that the era of the grand normative systems is past.

For readers, finally, who want a more detailed and comprehensive analysis of personality psychology and its evolution over time, I suggest they begin with Corr and Matthews (2009), John et al. (2008), and Dumont (2010). These will also lead them to many other valuable sources. To follow the development of this discipline, readers are urged to regularly consult the Annual Review of Psychology, Journal of Personality and Social Psychology, European Journal of Personality, Developmental Psychology, and other respected periodicals that publish articles in this domain.

Abstract

The connection between personality and psychopathology has been studied for centuries. In the current article, we provide an overview of contemporary research in the field. We begin with a review of trait models of personality and the current psychopathology classification system in use. We discuss the link between normal personality traits and personality disorders and other types of psychopathology and conclude with a discussion of different theoretical perspectives explaining the personality–psychopathology connection.

The link between personality and psychopathology has been long-recognized, dating back to ancient Greece and Hippocrates' discussions of the four humors. The four essential fluids of the body – phlegm, blood, bile, and black bile – were thought to determine temperament. Depending on the dominant humor, one could be phlegmatic, sanguine, choleric, or melancholic, and each type had an accompanying set of attributes. An imbalance in these humors led to symptoms of illness, and therefore temperament was thought to be connected to all disease, physical or mental. Later, in the nineteenth century, Darwinian-influenced perspectives on the personality–psychopathology link arose. These were evolutionary perspectives, depicting mental illness as a genetically based character deficiency. Stemming from this was Freud's influential theory of the stages of character development, from the primitive to the more complex, and associated psychopathology (Maher and Maher, 1994).

Contemporary psychologists and psychiatrists continue to explore this association, profiting from reliable and valid taxonomies of both personality and psychopathology. Trait models are contemporary models of personality that have gained consensus. These models emphasize traits as dimensions, covering the range from normal to disordered personality (vs a categorical distinction between the two). We begin with an overview of these trait models of personality. Next, we review the status of personality traits and disorders in the most current nosology put forth by the American Psychiatric Association, the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5; American Psychiatric Association, 2013). We note that the World Health Organization provides a classification system separate from the American Psychiatric Association's DSM, the International Classification of Diseases, which is currently being revised. Preliminary proposed changes to the eleventh edition, due for release in 2015, have not been made public; therefore, we limit our focus to the DSM. After reviewing personality traits and disorders in the DSM, we then review literature linking personality traits and other mental disorders. Finally, we conclude with a discussion of different theoretical perspectives explaining the personality–psychopathology connection.

Personality Trait Models

Allport offered a coherent definition of personality, writing, "Personality is the dynamic organization within the individual of those psychophysical systems that determine his characteristic behavior and thought" (1961: 28). Allport went on to elaborate on the key features of this definition, including the emphasis on individual differences. At the root of these individual differences are traits, dimensional tendencies to show consistent patterns of thoughts, feelings, and actions across time and situations. Further, personality traits are thought to be hierarchical, with broad traits subsuming more specific subfacets. A long-standing goal of personality psychologists has been to develop a taxonomy to characterize these broad trait dimensions. Although there is recognition that these dimensional traits cover a broad spectrum from moderate (i.e., normal) to extreme (i.e., abnormal) personality, some models focus more on the normal range, while others focus on the abnormal range of personality variation.

Models of Normal-Range Personality

Though many have fallen out of favor, multiple normal personality trait taxonomies have been put forth with the number of key personality traits ranging from two (Block and Block, 1980) to as many as twenty (Gough, 1987). Today two models, the Big Three and the Big Five, receive the most attention in the literature. The three-factor model varies somewhat across researchers and measures in terms of trait labels, however the essence of the constructs is the same. The models include positive temperament, negative temperament, and constraint (vs disinhibition; Tellegen and Waller, 2008; Watson and Clark, 1993) or parallel constructs such as extraversion, neuroticism, and psychoticism (Eysenck and Eysenck, 1976).

The Big Five, born out of the lexical tradition, represents an expanded taxonomy. Beginning with Allport's efforts (Allport and Odbert, 1936) and continuing for a quarter of a century (Tupes and Christal, 1992), trait terms were amassed from the English language dictionary and were subsequently factor analyzed. Across different samples, five factors emerged. These include extraversion (positive affectivity), agreeableness (vs antagonism), conscientiousness (constraint), emotional stability (vs neuroticism or negative affectivity), and openness to experience (or intellect and unconventionality; Lynam and Widiger, 2001). Tremendous empirical support for the Big Five has surfaced in the past few decades, as the same five-factor structure is found in numerous populations and settings (Costa and McCrae, 1988, 1994; De Raad et al., 1998;

Halverson et al., 1994; McCrae and Costa, 1990, 2003; Van de Vijver and Valchev, in press).

Another strength of the Big Five model is that it captures commonalities among most existing trait taxonomies (for an overview of how the Big Five maps onto other popular personality trait models, see John et al., 2008: 115). This hierarchical nature of personality traits allows us to reconcile seemingly distinct trait taxonomies, such as the Big Three and Big Five. For example, positive emotionality/temperament from the three-factor models is akin to extraversion, and negative emotionality/temperament is akin to neuroticism, while constraint (vs disinhibition) subsumes agreeableness and conscientiousness (openness does not appear in the three-factor models reviewed here). The three-factor models emphasize what one might call superfactors, while the Big Five is an extension of these broad domains (Markon et al., 2005). Though some have criticized the Big Five model for diminishing the complex schema of personality to only five traits, the purpose of the model is to "provide a scientifically compelling framework in which to organize the myriad individual differences that characterize humankind" (Goldberg, 1993: 27).

We can garner a more nuanced view of one's personality by considering the lower-order facets of the broad traits (Hong and Paunonen, in press). According to Costa and McCrae's (1995) model of the Big Five, there are six facets within each of the five domains. For example, they suggest that the domain of neuroticism consists of the more specific facets of anxiety, angry hostility, depression, self-consciousness, impulsiveness, and hostility. In this model, conscientiousness consists of competence, order, dutifulness, achievement striving, self-discipline, and deliberation (Costa and McCrae, 1995). Different models may identify a different lower-order structure. In particular, much work has been carried out on the lower-order structure of conscientiousness. In one study integrating lexical and questionnaire studies, five facets of conscientiousness emerged including industriousness, orderliness, impulse control, reliability, and conventionality (Roberts et al., 2005). Developing a consensus of the lower-order structure of each of the Big Five is critical because facets have better predictive validity than broad traits (Paunonen and Ashton, 2001), they show different developmental patterns (Jackson et al., 2009) and they can facilitate a better understanding of the client in clinical practice.

Models of Disordered Personality

Dimensional models of disordered personality have also been put forth. Two widely used measures of disordered personality traits are the *Schedule for Nonadaptive and Adaptive Personality* (Clark, 1993) and the Dimensional Assessment of Personality Pathology (Livesley and Jackson, 2009), consisting of 12 and 18 scales, respectively. Findings suggest these scales make up four broad, higher-order traits, which are similar, yet not identical, to those found in models of normal personality. Emotional dysregulation, dissocial behavior, inhibition, and compulsivity resemble neuroticism, (dis)agreeableness, (lack of) extraversion, and conscientiousness, respectively (Livesley et al., 1998; O'Connor and Dyce, 1998; Widiger, 1998). There is a parallel to each of the Big Five except openness. In addition to these four pathological traits, it has been argued that a distinct fifth factor is necessary to account for the variance in pathological personality functioning. This fifth trait has been labeled oddity or peculiarity (Watson et al., 2008). Some have posited that models of normal and abnormal personality should be integrated into a single hierarchy (Markon et al., 2005). For example, Watson et al. (2008) proposed a Big Six model that includes both normal and abnormal traits, including the Big Five and oddity.

Personality Traits and Disorders in the DSM

As discussed, these models highlight the idea that traits are dimensional, with abnormal personality representing extreme variants of normal-range traits. This counters the long-held categorical conceptualization of abnormal personality in the DSM. This perspective regards personality disorders (PDs) as "qualitatively distinct clinical syndromes" (American Psychiatric Association, 2013: 646). Ten specific PDs are defined and these are split into three clusters based on descriptive similarities. Cluster A includes paranoid, schizoid, and schizotypal PDs; Cluster B includes antisocial, borderline, histrionic, and narcissistic PDs; and Cluster C includes avoidant, dependent, and obsessive-compulsive PDs. A specific number of criteria must be met in order for a PD to be diagnosed. For example, antisocial PD is diagnosed if a patient meets at least three of seven criteria, including failure to conform to social norms with respect to lawful behaviors, deceitfulness, impulsivity, irritability and aggressiveness, reckless disregard for safety, consistent irresponsibility, and lack of remorse.

Each of these 10 PDs has been linked with normal personality traits (Crego and Widiger, in press). Saulsman and Page (2004) offered a meta-analysis documenting the relationship between each PD and the Big Five. Some similarities among PDs were uncovered (e.g., high neuroticism and low agreeableness are characteristic of most PDs) yet they also concluded that most PDs have a distinct personality trait profile. For example, antisocial PD, characterized by a pervasive pattern of disregard for the rights of others, is marked by low agreeableness and conscientiousness. Extraversion also shows strong relationships with most PDs, though the direction of that relationship varies across PDs. Extraversion is positively related to histrionic and narcissistic PDs, as individuals with histrionic PD crave attention and are often flirtatious and dramatic and those with narcissistic PD often demonstrate grandiosity in their beliefs and behavior. Extraversion is negatively related to schizoid, schizotypal, and avoidant PDs, on the other hand, as individuals with these PDs demonstrate a lack of interest in, or anxiety regarding, interpersonal contact and relationships. Conscientiousness shows some relations with PDs, though this finding is not as robust as for neuroticism, agreeableness, and extraversion, and openness shows no strong relationship with any PD. Samuel and Widiger (2008) extended this meta-analysis by

concentrating on the specific facets of the broad traits and largely replicated the findings of Saulsman and Page.

Numerous problems with the categorical perspective have been cited repeatedly in the literature (e.g., Widiger, 2003). These include a lack of qualitative distinction between normal and abnormal personality, heterogeneity within diagnostic categories, and excessive comorbidity. Critics of the categorical perspective argue that normal-range personality traits and those specific to PDs overlap considerably and share a parallel structure in genetic and environmental components (Livesley et al., 1998). They also contend that the categorical system's practice of using a subset of items to meet diagnostic threshold often results in incongruence between individuals who share the same diagnosis (Trull and Durrett, 2005). Two individuals meeting the diagnosis for antisocial PD, for example, may share all or no symptoms. Proponents of the dimensional system argue that the categorical system's difficulty with excessive comorbidity between PD diagnoses could be reproduced and better explained with a dimensional model. Clinicians would be better able to conceptualize their patients without the constraints of the DSM-defined PDs, and researchers would not need to unnecessarily exclude a majority of patients targeted to a study due to comorbidity (Krueger, 2013).

Given these criticisms and mounting support for integrative hierarchical models of personality dimensions, the authors of DSM-5 spent a great deal of time debating how to best conceptualize PDs and reflect that conceptualization in the diagnostic criteria. Many proposed replacing the categorical system with a dimensional model, but the authors were not able to arrive at a consensus approach on how best to do this (Krueger, 2013). Instead, DSM-5 offers an additional dimensional perspective of PDs in addition to the preexisting categorical one from DSM-IV-TR (American Psychiatric Association, 2000). Inclusion of both models was done to maintain current clinical practice while offering an alternative that addresses the numerous problems with the prior diagnostic system (American Psychiatric Association, 2013: 761). Section II contains the same diagnostic criteria for 10 specific PDs from DSM-IV-TR, while Section III contains the alternative dimensional model. In this model, "personality disorders are characterized by impairments in personality *functioning* and pathological personality *traits*" (p. 761; emphasis in original). While there are a few similarities across Sections II and III, such as criteria including stability and pervasiveness across personal and social situations, two key changes are emphasized in Section III. First is the evaluation of disturbances in self and interpersonal functioning on a five-point continuum ranging from no to extreme impairment. The second key change is the use of 25 specific pathological personality trait facets organized into five broad domains including negative affectivity, detachment, antagonism, disinhibition, and psychoticism. These five domains align, respectively, with the opposite poles of emotional stability, extraversion, agreeableness, and conscientiousness from the Big Five model, as well as the oddity/peculiarity trait from models of abnormal personality. These can be assessed with the Personality Inventory for DSM-5 (Krueger et al., 2013) with self- or informant-reports. Section III recognizes 6 of the 10 specific Section II disorders, including antisocial, avoidant, borderline, narcissistic, obsessive-compulsive, and schizotypal PDs. These six are differentiated according to the manner in which their disturbances in self and interpersonal functioning are manifest, as well as their defining pathological personality traits. That is, each disorder has a unique personality trait profile. Antisocial PD, for example (in addition to impairment in personality functioning), is characterized by six out of seven pathological personality traits, including manipulativeness, callousness, deceitfulness, and hostility (all facets of antagonism), in addition to risk taking, impulsivity, and irresponsibility (all facets of disinhibition). Section III offers the first step toward adopting a complete dimensional perspective of PDs.

Personality and Nonpersonality Disorder Psychopathology

Although personality traits connect most obviously with PDs, there is a plethora of research indicating a link between personality and other types of psychopathology as well. Before delving into a review of this research, it is important to first discuss the organization of (non-PD) mental disorders in the DSM-5, which will provide a framework to guide the discussion on the personality–psychopathology link. Unlike DSM-IV-TR, DSM-5 recognizes spectra of disorders that share common neural substrates, genetic and environmental risk factors, biomarkers, and temperamental antecedents, among other things (Andrews et al., 2009). Disorders within each spectra are situated in adjacent chapters. The spectra are also positioned to reflect developmental course, with disorders beginning in childhood (i.e., neurodevelopmental disorders, the schizophrenia spectrum, and other psychotic disorders) positioned first, and neurocognitive disorders, which have an onset of adulthood, falling at the end. Two clusters, internalizing and externalizing disorders, with adolescent or early adult onset lie in between. Internalizing disorders are those characterized by anxiety, depressive, and somatic symptoms and externalizing disorders are those characterized by impulsive, disruptive conduct, substance use, and other addictive symptoms (American Psychiatric Association, 2013: 13). The ensuing discussion involves the connection between personality traits and internalizing and externalizing disorders.

There are a number of published studies documenting the relationship between specific mental disorders and personality traits in specific clinical samples. Given space limitations and our objective of presenting a comprehensive overview of the personality–psychopathology connection, we limit our review to meta-analyses and epidemiological studies of multiple disorders. Trull and Sher (1994) provided a first look at the connection between the Big Five and multiple (non-PD) disorders in a nonclinical sample. Individuals were assessed for multiple lifetime diagnoses including substance use disorders, several anxiety disorders, and major depression. In general, neuroticism, extraversion, and conscientiousness were the traits most highly related to the various disorders. Most substance use disorders were characterized by high neuroticism and openness, and low extraversion,

agreeableness, and conscientiousness. Anxiety disorders showed a similar personality profile to substance use disorders. Any lifetime anxiety disorder showed elevated neuroticism and openness, and low extraversion, agreeableness, and conscientiousness. More specific anxiety disorders showed a similar pattern, though in some cases, the effects were not significant (i.e., the diagnosed group was not significantly different from the nondiagnosed group). The one exception was simple phobia where no differences were observed between the diagnosed and the nondiagnosed group. Major depression showed the same personality profile again; the diagnosed group had elevated levels of neuroticism and openness and lower levels of extraversion and conscientiousness. They were lower on agreeableness, though this difference was not statistically significant. In addition to documenting the personality profiles of diagnostic groups relative to those with no diagnoses, Trull and Sher confirmed that the Big Five provides clinically useful information by showing that Big Five scores accounted for a significant amount of variance in all diagnoses except simple phobia beyond that accounted for by a measure of psychopathology.

Krueger and colleagues extended the work of Trull and Sher (1994) with a longitudinal study of a representative birth cohort (Krueger et al., 1996). Age 18 Multidimensional Personality Questionnaire (MPQ; Tellegen and Waller, 2008) personality profiles of members of four diagnostic groups (affective disorder, anxiety disorder, substance dependence disorder, and conduct disorder) were compared with a control group, individuals with no diagnoses. The disorders were assessed at ages 15, 18, and 21. At the broad-factor level, compared with the control group, the affective disorder, substance dependence, and conduct disorder groups at age 18 scored low on positive emotionality and constraint, and high on negative emotionality (there was a greater distinction among the diagnostic groups at the level of the more specific scales). The anxiety disorder group scored low on positive emotionality and high on negative emotionality. These correlations between the age 18 personality traits exhibited a consistent pattern with age 15, 18, and 21 mental disorders. Using the same longitudinal data set, Krueger (1999) followed up by examining whether the age 18 personality traits predicted age 21 diagnostic membership above and beyond age 18 diagnostic membership. Greater negative emotionality at age 18 increased the odds of being diagnosed with affective disorder at age 21. Greater negative emotionality and constraint increased the odds of an anxiety disorder diagnosis. Increased negative emotionality and decreased constraint increased the odds of substance dependence disorder as well as antisocial PD.

Krueger and colleagues also examined the relationship between mental disorders and personality traits, again as measured by the MPQ, in a large population-based study (Krueger et al., 2001). In men and women, negative emotionality was positively correlated with an internalizing factor (including major depressive episode, panic disorder, simple phobia, and social phobia), and constraint was negatively correlated with an externalizing factor (including adult antisocial behavior, conduct disorder, alcohol dependence, and drug dependence). Positive emotionality had a negative correlation with the internalizing factor for women only.

Kotov and colleagues carried out a comprehensive meta-analysis of studies on the association between personality and internalizing and externalizing disorders, providing effect sizes to indicate the strength of relationship between them (Kotov et al., 2010). Specifically, they considered six broad personality traits, including extraversion/positive emotionality, agreeableness, conscientiousness, disinhibition, neuroticism/negative emotionality, and openness. Neuroticism showed the strongest association with mental disorders, with some effect sizes exceeding 2.0, followed by low conscientiousness. Low extraversion was fairly consistent across disorders, though the magnitude of the effect was smaller than for neuroticism and conscientiousness. Disinhibition better distinguished among disorders; the strongest and most consistent association was with substance use disorders. Low agreeableness was also related to substance use disorders, though to a lesser degree than anticipated. Openness showed no strong pattern of association with mental disorders. Further, Kotov and colleagues examined the personality profiles of clusters of disorders, examining externalizing (substance use disorders) and two clusters of internalizing disorders, distress (depressive disorders) and fear (anxiety disorders). The distress and fear profiles were markedly similar, though the distress cluster scored slightly higher on all traits other than openness. The substance use disorder cluster exhibited a distinct profile with elevated levels of disinhibition and extraversion and lower levels of neuroticism and agreeableness.

In sum, high neuroticism (negative emotionality) and low conscientiousness and extraversion (positive emotionality) are overwhelmingly associated with most mental disorders. Externalizing disorders are typically set apart from internalizing disorders by increased disinhibition (low conscientiousness coupled with low agreeableness). These findings are robust, and therefore the importance of personality traits in mental disorders cannot be ignored.

Explaining the Personality–Psychopathology Link

As evidenced by the collection of studies reviewed here, personality traits are closely linked with multiple types of mental disorders. In this next section, we consider six explanations for this relationship. Four models (vulnerability, pathoplasty, scar, and complication) consider personality and psychopathology as distinct constructs, while two models (common cause and spectrum) treat them as having common underpinnings. We use the well-established connection between low conscientiousness (and its facets of industriousness, impulse control, orderliness, reliability, and conventionality; Roberts et al., 2005) and increased substance use to illustrate each (Kotov et al., 2010; Walton and Roberts, 2004).

The vulnerability model is a causal model, suggesting that premorbid personality traits can act as risk factors, predisposing an individual to mental disorder. For example, preexisting low conscientiousness puts one at risk for developing substance use disorders. Those low on impulse control might be more likely to engage in binge drinking. The pathoplastic relationship hypothesis suggests that personality traits influence mental

disorder once the disorder is already developed. That is, the course of illness, its expression over time, and its response to treatment are susceptible to the influence of personality traits. For example, substance abuse problems might continue to worsen in individuals with low conscientiousness.

While the vulnerability and pathoplasty models consider the influence of personality on mental disorders, the scar and complication models consider the influence of mental disorders on personality. Like the vulnerability model, the scar model is causal, positing that mental disorders have a direct effect on personality traits. For example, those engaging in excessive substance use might exhibit decreased levels of key characteristics of conscientiousness, such as industriousness and reliability, as a result of their misuse. That is, they might be less like to complete tasks, follow through with responsibilities, etc. The complication model follows from the scar model, but the effect of the disorder on personality traits is hypothesized to be temporary, lasting only the duration of the disorder. For example, individuals abusing alcohol or drugs would be much more likely to lack impulse control when their disorder expression is heightened, but their impulse control levels would become more normative once the disorder was treated.

Finally, the common cause and spectrum models suggest that personality traits and psychopathology are not distinct constructs but instead share a common underpinning. The common cause model posits that personality and psychopathology share a single basis. A common root, such as a common genetic risk factor, would explain the overlap in conscientiousness and substance use (Vrieze et al., 2013). According to the spectrum model, personality and psychopathology are different manifestations of a common process. Some have argued that conscientiousness and substance use are part of an externalizing spectrum (Eaton et al., 2010).

It has been argued that these six hypotheses are not mutually exclusive and that more than one may appropriately describe the personality–psychopathology relationship (Andersen and Bienvenu, 2011; South et al., 2010). The cause of the relationship could vary from person to person or from disorder to disorder. While there is some evidence supporting each model, further longitudinal data are necessary to distinguish among them. For example, we cannot appreciate the interplay between conscientiousness and substance use without tracking the lifetime course of one in light of the developmental course of the other. Nevertheless, we argue that the common cause and spectrum models are in line with the research reviewed in the sections above, demonstrating that there is no distinction between normal and abnormal functioning but rather they fall along a common continuum with abnormal functioning representing extreme expressions of normal personality traits (Widiger, 2011).

Conclusion

There is a large body of research describing the associations between personality and psychopathology, which has been facilitated by a growing consensus regarding personality and psychopathology taxonomies. Understanding these associations is important for several reasons. Research on the personality–psychopathology link has helped us understand comorbidity, and we have seen changes to classification systems as the result of this understanding. For example, in the DSM-5, we no longer see a divide between Axis I and Axis II disorders, there is greater appreciation for developmental continuity, and there is recognition of spectra of disorders. Continued research will not only help us refine our classification systems, but will help us gain insight into the etiology of psychiatric conditions and improve prevention and intervention efforts.

Abstract

Traits have been defined as dimensions of individual differences in tendencies to show consistent patterns of thoughts, feelings, and actions. Such consistent patterns are supported by evidence, and robust dimensions of personality differences have been identified. Traits are best measured by multiple indicators, and as they reflect general trends of thinking, feeling, and acting in trait-consistent ways, they predict socially important criteria including job performance, educational attainment, physical and mental health, longevity, and subjective well-being.

What is a trait? McCrae and Costa (2003) define traits as "dimensions of individual differences in tendencies to show consistent patterns of thoughts, feelings, and actions" (p. 25). *Dimensions of individual differences* means that traits refer to differences between persons, assuming that these differences are continuous. For example, by saying that Anne is sociable, we mean that Anne's sociability is above average in a population of persons who differ continuously in their sociability. The deviations from the population average may be large, small, or nil, the distributions of most traits approximating the familiar normal curve. In psychometrics, trait models are distinguished from class models. Whereas trait models imply continuous differences between persons, class models imply qualitatively different personality types (De Boeck et al., 2005). An example of a class model having received considerable empirical support (Chapman and Goldberg, 2011) is Block's (1971) distinction between resilients, overcontrollers, and undercontrollers.

Patterns of thoughts, feelings, and actions means that traits do not describe single and specific habits like smoking or talking in a loud voice, but broad individual differences in experience and behavior. Moreover, *tendencies* implies that traits influence but do not determine persons' experience and behavior. Traits matter, but situations matter too (Fleeson, 2004). Traits are therefore conceived as dispositions implying probabilities: Persons with a high trait level are more likely to show trait-consistent behavior than persons with a low trait level, but probabilities of exactly 1.0 do never occur. For example, extraverts are more likely to seek the company of others than introverts, but even an extremely extraverted person may sometimes prefer to be alone.

Consistent means that differences between persons reflecting traits are stable across time and situations. That Anne has the trait of being gregarious implies that she is more extraverted than others not only today, but will also be so next year. Nevertheless, some long-term change in personality occurs: First, there are age trends. For example, extraversion tends to decline with age. Second, the rank order of personality differences is largely but not perfectly stable (Lucas and Donnellan, 2011). If Anne is more extraverted than her classmate Bill at age 15, there is a slight probability that Bill will be more extraverted than Anne 20 years later. Moreover, rank-order stabilities change across the life span: Personality differences tend to stabilize until the sixth decade of life, but afterward stability decreases (Lucas and Donnellan, 2011; Roberts and DelVecchio, 2000). Finally, personality differences are manifested across multiple situations. For instance, extraverts seek the company of others not only during leisure but also in the workplace. It is an empirical issue, however, across which situations trait-relevant behaviors generalize. Among others, this is linked to the breadth of the trait. There are narrower traits predicting behavior in a more restricted range of situations than do broader traits (Hampson et al., 1986). An example is *helpful* versus *kind*: Whereas helpful persons tend to support others being in need of help, kind persons tend to please others in a broader range of situations.

Personality psychologists distinguish between traits and states. Whereas traits are largely (but not perfectly) stable, states are transient. Traits can be understood as frequencies that relevant states occur. Measuring personality states repeatedly, Fleeson (2001) compared the variation of personality states within individual persons with the variation between persons in their mean state levels, averaged across multiple occasions: For most traits, more variance was found within than between persons. For example, the participants' conscientiousness varied more from one occasion to the next than that the averaged levels of conscientiousness varied from one participant to the other. This shows that situations influence behavior, but it is useful to distinguish between two varieties of situational influences: First, variability within persons may reflect main effects of situations leaving the persons' rank order unchanged. A hypothetical example would be that most persons are more anxious before than after an exam, and those being more anxious before are so after the exam as well. As the rank order of persons remains stable across situations here, such a pattern would strongly support a trait model of personality, exemplifying that situational influences are entirely compatible with a trait model of individual differences. Second, the rank order of persons may vary from one situation to the next, that is, there may be Person × Situation interactions, implying that the individual differences are not perfectly consistent across situations.

As a matter of fact, cross-situational consistencies are moderate if behavior in a single setting is compared with behavior in another single setting. Across 15 different single settings (e.g., introducing oneself, telling a joke), Borkenau et al. (2004) obtained an average reliability-corrected cross-situational consistency coefficient of 0.43. But cross-situational consistencies tend to be much higher if the average level of trait-relevant behavior in a *set* of settings is compared with the average level of trait-relevant behavior in another *set* of settings

(Epstein, 1979; Fleeson, 2001, 2004). Thus traits are not particularly useful for predicting single behaviors in specific situations, but they are highly useful for predicting general trends of thinking, feeling, and acting in trait-consistent ways. For example, a conscientious person will act, on average, in more organized ways than a less conscientious person. Such tendencies strongly influence important outcomes in various domains of life. And because these tendencies are also quite stable across time, traits predict numerous socially important criteria (Ozer and Benet-Martínez, 2006), among them life satisfaction (Steel et al., 2008), longevity (Bogg and Roberts, 2004; Hampson and Friedman, 2008), academic achievement (Poropat, 2009), and career success (Connelly and Ones, 2010).

But the view that personality should be conceptualized in terms of traits has not remained undisputed. Mischel and Shoda (1995, 2008) suggest studying intraindividual patterns of variability instead of cross-situationally consistent patterns of behavior. For example, whereas Anne may be more talkative in large groups than in dyadic settings, the reverse may be true of Bill. As far as such situation–behavior interactions are stable across time, Mischel and Shoda (2008) argue that they are highly diagnostic of persons' cognitive and affective processes. This is frequently referred to as the *social-cognitive approach* to personality.

Measuring Traits

Measuring tendencies for showing consistent patterns of thoughts, feelings, and actions via behavior observations would be extremely laborious: multiple behaviors by numerous persons would have to be observed and coded repeatedly in multiple situations. Yet even then many thoughts and feelings would escape their observation. Therefore, most researchers of personality have relied on self-reports, harnessing that persons are aware of their own thoughts, feelings, and actions in many situations, and remember them over long periods of time. But self-reports are not without problems: People may be unaware of their unconscious motives, and their memories may be distorted. Moreover, persons may misrepresent themselves knowingly or unknowingly, to protect their reputation and self-esteem (Paulhus, 1984; Vazire, 2010). Furthermore, as the only persons who can provide self-reports are the to-be-described persons themselves, their objectivity cannot be ascertained (Hofstee, 1994).

Researchers have therefore looked for convenient additional methods for measuring personality traits, and have identified descriptions by knowledgeable informants like peers and spouses as a useful complement (Vazire, 2006). Reports by knowledgeable informants seem to be less valid measures of neuroticism-related but more valid measures of intellect-related traits than self-reports (Vazire, 2010). Moreover, other-ratings seem to be more valid predictors than self-reports of academic achievement and job performance, and they predict incrementally to self-reports (Connelly and Ones, 2010). Some authors therefore argue that aggregates of self-reports, informant reports, and maybe additional measures provide the best possible assessment of personality traits (Letzring et al., 2006).

Most measures of personality are scales consisting of multiple items being correlated with each other, each item alluding to a somewhat different facet of the trait. For example, a scale measuring neuroticism may comprise items addressing feelings of inferiority and items addressing feelings of anxiety. The responses to these items are aggregated (usually summed up). There are several advantages to such multiitem scales over one-item measures of traits: First, multiitem scales allow for more fine-grained distinctions between trait levels. For example, if responses are provided on five-point rating scales, and a scale consists of 10 items, there are 41 possible scores. Second, the reliability (precision) of the measures increases with the number of their items, as random errors cancel each other out. Third, the content being common to the items and reflected in their covariances is highlighted, whereas item-specific variances are suppressed. That is desirable as traits are quite general patterns of thoughts, feelings, and actions, not the quite specific behaviors and experiences that single items ask for.

Sources of Traits

Why do persons differ in their traits? Ultimately, genetic as well as environmental factors are influential, and quantitative behavior–genetic research has gone for estimating their relative contributions. Most of this kind of research relies on the classical twin design, comparing the similarity of monozygotic (MZ) twins with the similarity of dizygotic (DZ) twins reared in the same household. This design allows partitioning the phenotypic (observed) variance into three components: (1) variance accounted for by the effects of genes, (2) shared environmental variance contributing to the similarity of persons reared together independent of their genetic relatedness, and (3) nonshared environmental variance not contributing to the similarity of persons. Higher correlations between MZ twins than DZ twins suggest genetic, similar and positive twin correlations for MZ twins and DZ twins suggest shared-environmental, and less-than-perfect correlations between MZ twins reared together suggest nonshared-environmental influences.

Most twin studies on personality traits relied on self-reports, some of them studying very large samples. Put in a nutshell, the core finding of these studies has been that genes and nonshared environment each account for approximately 50% of the individual differences in personality traits, whereas shared environmental influences seem to be very small (Jang et al., 1996). Thus being raised in the same household seems to contribute negligibly to similarity in personality. But twin studies relying on self-reports do not allow separating nonshared environmental influences from measurement error. Measurement error can be appropriately controlled, however, if each of the twins under study is described by at least two informants. Running such a study and controlling for measurement error, Riemann et al. (1997) found that genes and nonshared environment account for approximately 70 and 30% of the personality differences, respectively.

Finding genetic influences on personality traits is interesting but raises a lot of questions. One question is whether specific genes can be located in the genome that account for the observed individual differences. This is the field of molecular behavior genetics. Here, the frequencies of different gene variants, so-called alleles, are compared between groups of persons scoring high versus low on a trait. One early finding of this line

of research has been that a sequence-length polymorphism (the occurrence of either a short or a long allele) at a gene locus in the regulatory region of the serotonin transporter gene (5-HTTLPR) accounted for 3–4% of the variance in anxiety-related traits (Lesch et al., 1996). Later on, it was reported that this genotype interacts with environmental stressors to the effect that the number of stressful life events raises the risk of a major depressive episode only among persons with at least one short variant of this allele (Caspi et al., 2003). Such findings are potentially important as they may help explain why some persons seem to be invulnerable to the effects of environmental stressors whereas others are not. In a meta-analysis of 14 relevant studies, however, Risch (2009) found a main effect of the number of stressful life events only, but neither a main effect of the genetic polymorphism as reported by Lesch et al. (1996), nor a gene–environment interaction as reported by Caspi et al. (2003).

Such failures to replicate are not uncommon in allelic association studies, probably reflecting that (1) personality traits are influenced by thousands of genes, the effect of each single gene being very small; and (2) there are millions of genetic polymorphisms in the human genome that might be related to human behavior, resulting in a high probability to occasionally find false-positive gene–behavior associations (McCrae et al., 2010). But much molecular-genetic research on personality and psychopathology is going on, and some genes that exert a strong influence on behavior might yet be identified.

Another issue is how genes affect behavior. After all, genes code for proteins, or they regulate the coding of proteins by other genes. Thus their effects on behavior are indirect. There are several possible pathways, many of them involving neurotransmitters, i. e., chemical substances transmitting information in the brain. Cloninger (1987) suggested three major brain systems modulated by different neurotransmitters: A behavioral activation system (BAS) modulated by dopamine and accounting for individual differences in novelty seeking (a trait resembling extraversion), a behavioral inhibition system (BIS) modulated by serotonin and accounting for individual differences in harm avoidance (a trait resembling neuroticism), and a behavioral maintenance system modulated by norepinephrine and accounting for individual differences in reward dependence (a trait resembling agreeableness). Likewise, Gray and McNaughton (2000) suggested a BAS organizing responses to signals of reward, a fight-flight-freezing system organizing responses to signals of punishment, and a BIS being activated in cases of conflict, that is, if a stimulus signals potential reward as well as potential punishment. Smillie (2008) discusses possible genetic sources of individual differences in these three systems.

Which Traits Should Be Measured and Studied?

In major languages like English, there are thousands of personality-descriptive terms, many of them describing traits. Measuring all of them would be extremely laborious, unacceptable to research participants, and redundant because discrete terms may denote very similar (e.g., friendly and kind) or opposite (e.g., friendly and hostile) traits. Personality researchers have therefore sought to identify 'basic dimensions' of personality that research should focus on. The data-analytic method mostly used here is factor analysis that accounts for correlations between observed variables, for example scores on multiple personality scales, by their loadings on common latent variables called *factors*. For example, that scales measuring anxiety are substantially correlated with scales measuring depression has been interpreted as evidence that anxiety and depression are facets of a common latent factor labeled either Neuroticism or – its opposite – Emotional Stability. Several factor models of personality have been suggested by authors like Guilford, Cattell, Eysenck, and Tellegen, but the currently most popular model is the Five-Factor model of personality advocated by several authors, most prominently Goldberg (1990) and McCrae and Costa (1987).

The Five-Factor model is an outcome of the lexical approach to personality that is based on the lexical hypothesis. As the factors being found depend on the variables being entered into a factor analysis, identifying the basic factors of personality requires that the traits in the analysis are representative of all traits. The lexical hypothesis posits that most of the socially relevant and salient personality characteristics have been encoded in the natural language. Thus, the personality vocabulary contained in the dictionaries of a natural language provides an extensive, yet finite, set of attributes that the people speaking that language have found important in their daily interactions (Goldberg, 1981). Therefore, researchers have culled thousands of trait-descriptive terms from comprehensive lexica, and grouped them into clusters of similar terms. These clusters of trait-descriptive terms were then used for describing actual persons, and the descriptions were correlated. Five recurrent factors were identified, and 'nothing else of any consequence' (Tupes and Christal, 1992). Moreover, very similar factors were found in descriptions by acquaintances on adjective scales, in self-reports on such scales, and in self-reports on personality questionnaires (McCrae and Costa, 1987).

Usually, these factors are labeled *Neuroticism*, *Extraversion*, *Openness to Experience*, *Agreeableness*, and *Conscientiousness*. This Five-Factor model is extremely useful by providing a common language for personality researchers thus helping them to coordinate their research efforts. In recent research on issues like life-span development and rank-order stability of personality (Lucas and Donnellan, 2011), interjudge agreement on personality traits (Connelly and Ones, 2010), prediction of academic achievement (Poropat, 2009), prediction of job performance (Connelly and Ones, 2010), and the relationship between personality and subjective well-being (Steel et al., 2008), personality differences have been framed in terms of the Five-Factor model.

That does not imply that traits not covered by the Five-Factor model are unimportant. First, personality traits are ordered hierarchically, the Five-Factor model describing personality differences at a broad level. There are also more specific traits describing personality at a narrower level, like anxiety and depression that may both be understood as facets of neuroticism. Second, some researchers are less interested in the basic dimensions of personality and their facets, than in traits they consider as useful for their special purposes. Thus Watson and Tellegen (1985) were particularly interested in current and long-term affect. Studying the structure of

mood, they identified two dimensions of core affect, Positive Activation contrasting excitement at the high pole with depression at the low pole, and Negative Activation contrasting distress at the high pole with calmness at the low pole (Watson et al., 1999). Individual differences in these dimensions were found to be quite stable across time (Watson and Walker, 1996).

And they are not independent of the dimensions of the Five-Factor model: Whereas Positive Activation is strongly associated with Extraversion, Negative Activation is strongly associated with Neuroticism. These findings gave rise to a distinction suggested by Elliot and Thrash (2002) between approach motivation subsuming Extraversion, Positive Activation, and a strong BAS, and avoidance motivation subsuming Neuroticism, Negative Activation, and a strong BIS.

Personality Traits and Socially Relevant Outcomes

That traits describe general trends to think, feel, and act in trait-consistent ways, makes them highly useful predictors of socially important criteria in several life domains. Ones and Viswesvaran (2011) summarized several meta-analyses concerning occupational outcomes, demonstrating that conscientiousness is a consistent predictor of overall job performance. This holds even across heterogeneous sets of professions and countries with validity coefficients ranging from 0.19 to 0.22. Furthermore, it was shown that conscientiousness predicts job satisfaction positively ($r = 0.26$), whereas it is negatively related to counterproductive work behavior ($r = -0.38$) and turnover ($r = -0.22$). According to a meta-analysis by Barrick et al. (2001), the other traits in the Five-Factor model are important for more specific job performance criteria: Whereas extraversion is positively related to managerial performance and training proficiency, neuroticism is negatively linked to successful social interacting, whereas agreeableness predicts successful teamwork, and openness to experience is associated with training proficiency. The importance of these traits is not limited to predicting performance. Neuroticism is additionally linked to satisfaction at work ($r = -0.29$) and to turnover ($r = 0.20$), whereas agreeableness is additionally related to counterproductive work behavior ($r = -0.28$) and turnover ($r = -0.27$; Barrick et al., 2001; Ones and Viswesvaran, 2011). Interestingly, the prediction of occupational outcomes from personality traits seems to be unique as it persists if socioeconomic status and cognitive abilities are controlled for (Ones and Viswesvaran, 2011; Roberts et al., 2007). Furthermore, turnover is predicted more strongly from conscientiousness, neuroticism, or agreeableness than from characteristics of the job like its complexity (Zimmerman, 2008).

Considering academic performance, the associations resemble those in the occupational domain. Conscientiousness is the best predictor of academic performance too. In a meta-analysis by Poropat (2009), conscientiousness correlated with Grade Point Average (GPA) at 0.19 quite independently of the level of intelligence. Agreeableness and openness to experience predicted GPA as well, although with smaller validity coefficients of 0.07 and 0.10, respectively. The correlation of GPA with openness to experience diminished marginally if intelligence was controlled for (Poropat, 2009). The latter result, combined with the positive relation of openness to experience to training proficiency (Ones and Viswesvaran, 2011), underlines the importance of openness to experience for being a successful student in various life domains.

Within the health domain, personality traits show consistent and unique effects on various outcomes like longevity, or physical and mental health processes. They seem to support or to hamper recovering from various diseases. Neuroticism was shown to predict higher overall mortality (Wilson et al., 2005), and to be associated with a higher risk of dying from particular illnesses such as cardiovascular diseases (Denollet et al., 2006; Shipley et al., 2007). Among patients suffering from chronic renal insufficiency, high neuroticism is associated with higher mortality (Christensen et al., 2002). In contrast, extraversion predicts a longer life (Wilson et al., 2005), and high conscientiousness is associated with lower mortality among renal patients (Christensen et al., 2002). Personality traits predict mortality uniquely even if socioeconomic (Roberts et al., 2007) and initial health status (Shipley et al., 2007) are controlled. In terms of risk factors for specific diseases, for example, cardiovascular diseases, studies showed that neuroticism and hostility (low agreeableness) are positively, whereas conscientiousness is negatively, associated with weight gain and increase of body mass index (Brummett et al., 2006; Niaura et al., 2000). Furthermore, conscientiousness is inversely related to adverse health behaviors (e.g., excessive alcohol and drug use, tobacco use, unhealthy eating) which are important contributors to poor health outcomes such as cardiovascular diseases (Bogg and Roberts, 2004).

Personality traits are associated with mental disorders as well. According to a meta-analysis by Kotov et al. (2010), neuroticism is directly related to depressive disorders, anxiety disorders, and substance abuse that are quite common in the adult population. The average effect size of neuroticism on all mentioned disorders was $d = 1.65$. In contrast, conscientiousness showed strong and consistently negative connections with mental disorders ($d = -1.01$), and the effect of extraversion was also negative but limited to fewer disorders (e.g., social phobia, dysthymic disorder). The same held for agreeableness and openness to experience that showed a few negative correlations to some kinds of substance abuse and to the dysthymic disorders, respectively.

Finally, personality traits predict subjective well-being. In a meta-analysis by Steel et al. (2008) neuroticism and extraversion were strong predictors of subjective well-being, with neuroticism being directly related to negative affect and inversely related to happiness and quality of life. In contrast, extraversion was directly related to positive affect, happiness, and quality of life.

To summarize, across various life domains such as occupation, education, health, and subjective well-being, personality traits, that is individual differences in tendencies to show consistent patterns of feelings, thoughts, and actions, predict numerous and socially important real-life criteria.

Abstract

The rapid advances in medical science over the past two decades have already changed the way medicine is practiced, but the acceleration of advances suggests that health care systems worldwide are facing a tsunami of new advances in understanding and in technology that will require radical reorganization of the health care system. The improved possibility of personalizing health care is one of the major drivers of change. Unfortunately, health care systems respond very slowly to innovation, and radical changes are almost impossible. In this article, we outline various changes that are expected to happen in the future in relation to personalized medicine, and discuss why behavioral scientists must participate in the reshaping of health care systems and the successful delivery of personalized care at the individual level.

What Is Personalized Medicine?

Historical Perspective

In its most basic sense, personalized medicine refers to the provision of the right drug to the right patient at the right time. Physicians, of course, correctly argue that they have practiced medicine this way for hundreds of years. Diagnosis of disease involved a family history, physical examination, and simple diagnostic tests (e.g., blood test or X-ray). For most diseases, only one or two therapies were available and physicians made their choice of treatment depending on various guidelines and their intuition based on previous experience with other patients. Very often, only a small proportion of patients with a specific disease responded to treatment, but the reasons for the successes and failures of these treatment methods were not clear.

New Advances Enhance Feasibility of Improving Personalized Care

Advances in understanding and technology have greatly changed this historical scenario. Physicians now often understand why some patients respond to treatment and others do not. New molecular understanding of disease sometimes allows for the categorization of patients into subgroups, each with different treatment options. Because of the increased precision of diagnosis and the stratification of patients into groups, the new medicine is often called 'precision medicine' or 'stratified medicine' (Allison, 2008). Nevertheless, in this article we will use the term personalized medicine to refer to these new approaches.

In the following sections, we will give examples of some of the biological and technological discoveries that are driving changes in medicine toward increasing personalized treatments. Many articles have discussed these changes and discussed their implications (Brücher et al., 2014). However, few articles have outlined the potentially important contributions that behavioral scientists must play in the new paradigms of medical practice.

Breadth of Changes

The onset of disease is a complex process involving interactions between the genetic makeup, environmental influences (including diet and gut bacteria), and behavior. Studies on cancer have led to the revolution of personalized medicine, and this article will use mainly examples from cancer. Nevertheless, personalized medicine is affecting all diseases, from metabolic diseases (e.g., diabetes mellitus) to autoimmune diseases (e.g., rheumatoid arthritis) and mental disorders (e.g., anxiety and depression). The challenges that face implementation of personalized treatment for cancer apply equally to other diseases.

Advances in genomics have created the greatest opportunities for personalized treatment. The development of specific biomarkers of disease, such as hormone receptors in breast cancer, and genetic profiles of the entire genome of patients are leading to increased stratification of cancer patients (Dancey et al., 2012). However, genomics goes beyond just diagnosing disease; genomic profiles can sometimes predict who will develop the disease, or who will be likely to respond (or not respond) to a specific therapy. The predictive potential of genomic profiles will require a higher level of interaction between health care professionals from several disciplines and patients and families in managing their health and health care.

Diagnosis and Screening

Precise diagnosis is essential in order to categorize individuals into the most appropriate group for treatment. The accuracy of the diagnosis depends on high sensitivity (i.e., very few false negative tests) and high specificity (i.e., few false positives) of the diagnostic tests. As interventions to improve health become increasingly complex and expensive, the feasibility and sustainability of the intervention depends on the accuracy and feasibility of the diagnostic test. In addition, since many interventions are only suitable for a small proportion of individuals with unique genetic or physiological traits, tests must be cost effective. For example, a test costing $100 becomes very expensive if only 1% of patients meet the criteria for receiving the intervention; detecting each responsive patient costs $10 000, a factor that must be included in cost–benefit analyses of the intervention.

Similarly, effective treatments may become uneconomic if the diagnostic test lacks specificity (i.e., has many false positive

results) and results in substantial numbers of individuals receiving an unnecessary, expensive intervention. The prostate-specific antigen (PSA) test for prostate cancer is an example of a test with poor specificity (Bunting et al., 2002). While a high proportion of individuals with early prostate cancer have this biomarker in their blood, many nonmalignant conditions also lead to an increase in PSA. Most countries no longer recommend routine PSA testing because it leads to many unnecessary biopsies and surgeries.

Treatment

Cancer results when an individual cell in the body acquires mutations in several pathways that regulate cell growth and survival (Hanahan and Weinberg, 2011). These mutations disrupt the regulation of cell division resulting in uncontrolled growth and cancer. Recent studies in gene sequencing and in understanding the regulation of cell division show that there are many routes to cancer, and that understanding the precise defects can sometimes lead to a novel therapy that targets the mutated pathway. For example, understanding that the unique Philadelphia chromosome abnormality in all patients with chronic myelogenous leukemia (CML) created an abnormal *abl* oncogene, which led to the development of Gleevec, a novel chemical that acts specifically on this abnormal protein and one other, the *kit* oncogene, which is mutated in the rare gastrointestinal stromal tumors (GIST). This therapy results in long-term survival of both CML and GIST and is the best example in cancer of how understanding the molecular basis of disease can lead to effective new therapies (Druker, 2009).

Another recent example is a new treatment for lung cancer. A small proportion of patients with lung cancer (5–15%) have alterations in a gene called ALK-1, and these patients undergo significant remissions in the disease following treatment with crizotinib, a specific inhibitor of ALK-1 (Gandhi and Janne, 2012).

In the United States, the FDA has approved over 30 targeted therapies for cancer. In most instances, the agencies that fund the therapies require a diagnostic test measuring a biomarker to ensure that the patient has the potential to respond to the therapy. Most biomarkers are either specific mutations, such as ALK-1 or abl, or for unique growth factor receptors, such as the HER2 receptor in some breast cancers (National Cancer Institute, 2013).

Pharmacogenetics will play a major role in developing personalized treatments. Most injectable or oral medications are metabolized and ultimately degraded and/or modified and excreted. However, individual patients metabolize drugs at different rates. Although metabolic pathways may be the same for the vast majority of people, there are interindividual differences in the activity of the enzymes that make up these pathways. Given the same dose of drug, this variation can result in marked differences between individuals in drug response (i.e., concentrations), depending on the rate of drug metabolism. Rapid metabolizers may get little benefit if the blood level of the drug never reaches the concentrations needed for a therapeutic effect. Conversely, a very slow metabolizer may have a higher than desired blood level leading to toxic side effects, such as for Warfarin, a commonly used drug for preventing thrombosis (Wheeler et al., 2013).

An additional diagnostic approach to identify those at risk of toxic side effects because of slow metabolic rates may involve behavioral and psychophysiological assessments, such as for Efavirenz, a commonly used nonnucleoside reverse transcriptase inhibitor, frequently prescribed in combination with other antiretroviral regimens (e.g., protease inhibitors) for the treatment of HIV (Sütterlin et al., 2010).

Prevention

According to a recent report from the World Health Organization, the two major causes of mortality in the developed world are cardiovascular disease and cancer. **Figure 1** shows the data for the 10 leading causes of death in high-income countries (The World Health Organization, n.d.); in developing countries, the same diseases are prevalent, but infectious diseases become more important. There are preventive strategies applicable to all of these causes. However, in almost all instances, the preventive intervention requires behavior modification: increased physical activity, eating a healthy diet (five portions of fruit and vegetables daily), smoking cessation, and participation in regular screening for diseases.

Tobacco use is the best example of the difficulty of changing behavior to improve health. The first warnings about the dangers of tobacco appeared in the 1950s with the report from the United Kingdom by Doll and Hill in 1954 on the high incidence of lung cancer in doctors who smoked, and finally the 1964 Surgeons General Report in the United States that identified smoking as the major cause of lung cancer in men (for review, see (Proctor, 2012)). These reports stimulated many efforts to reduce smoking, but in the past 50 years, smoking prevalence in North America has only decreased from 45 to 20% despite widespread acceptance that smoking is bad for health. In many parts of the Far East, rates exceed 50% and show no signs of decreasing (World Health Organization, 2008).

Palliative Care and End-of-Life Care

Palliative care is any treatment or procedure to alleviate symptoms or to slow the progression of disease rather than to attempt cure. Improving quality of life is the primary goal of palliative care processes. Palliative care can involve relief of

Figure 1 Leading causes of death in high-income countries (mortality/100 000). COPD, Chronic obstructive pulmonary disease.

pain, nausea, physical disabilities, and stress, and taking care of psychological and spiritual issues.

The advances in genomic characterization of neural receptors involved in pain and in the understanding of the physiological and psychological aspects of pain have increased the potential for personalized pain management. Approaches to chronic pain management involve a combination of analgesics, psychological support, and physical therapy, but the algorithms for pain management remain a work in progress (Bruehl et al., 2013).

End-of-life care refers to the support to patients and their families during and after death. Caregivers often fail to discuss death with patients and families dealing with life-threatening illnesses. The end result is that patients often die in situations that are not comfortable and compassionate, and family members do not receive adequate support for bereavement. Providing personalized information to terminally ill patients, i.e., information that strikes the balance between ensuring that patients and their families are fully informed and fostering adaptive coping that allows for hope has been found to be crucial for successful communication in medical settings, and in alleviating stress and improving well-being, even in those facing imminent death (Cavers et al., 2013; McLean et al., 2011).

Scotland, through the Scottish Partnership for Palliative Care, has created one of the most innovative programs to deal with end-of-life care. The program called 'Good Life, Good Death, Good Grief' focuses on individuals and their families in the recognition that there are many community and social and cultural aspects to end-of-life care (Scottish Partnership for Palliative Care, n.d.).

Implications for Health Care Systems

The advances associated with personalized medicine will have multiple effects both on the health care system and on the way individuals manage their own health.

The impending evolution from traditional health care approaches to a system that focuses on personalized, precision medicine requires a radical change to health care. Historically, health care has evolved into a slow evolutionary process with many new innovations in health care taking up to 15 years to go from confirmation in a clinical study to widespread adoption by health care professionals. This rate of evolution must accelerate dramatically for the health care system to provide the many benefits of recent research in the medical and behavioral sciences. The following sections outline a few of the most challenging issues.

Health Systems Facing a Tsunami of Change

Risk of Increased Costs

Many of the newly targeted therapies have very high costs, sometimes in excess of $100 000 per year. Funders of health care, usually governments or insurance companies, can only justify costs if these interventions are limited to those likely to benefit. A major challenge to health care systems will be to implement the new personalized approaches in a cost-neutral or minimal-cost process. This restructuring of health care systems will require elimination of noneffective procedures (e.g., routine health exams), and restriction of medications only to those most likely to benefit. The widespread off-label use of drugs must decrease.

Cost–benefit studies are already becoming standard in many countries before a new innovation is introduced and covered by the health system. The National Institute for Health and Care Excellence (NICE) system in the United Kingdom is leading the way in this process. NICE is developing a process to evaluate both health and social value benefits and the costs of any benefit (Shah et al., 2012). To help make the decision objective and not subjective, the expert teams from NICE calculate the cost of health benefits in terms of dollars (pounds) required to achieve 1 year of quality-adjusted life years (QALY). The calculation of a QALY considers increase in both life years and quality of life expected by the new treatment. Generally, if a new intervention costs more than £20 000–30 000/QALY, it will not be considered to have sufficient benefit to be recommended for routine use. Other countries are using a similar approach and a similar benchmark for implementation. However, funders sometimes make exceptions for expensive drugs used for very rare diseases. For example, Cerezyme (imiglucerase) is an enzyme replacement for individuals with Gaucher's disease, a hereditary disease with a deficiency in this enzyme (Doneda et al., 2013). Treatment costs $200 000 per year and patients must take the supplement for their entire life. Nevertheless, many countries have opted to cover the cost because of the benefits to patients and because the disease is relatively rare (~1/50 000 in the U.S. population).

Electronic Records and Data Management

A recent U.K. report, 'Realising the potential of stratified medicine' emphasized that collection of data is important and will require standardization of data collection, enhanced bioinformatics to analyze the data, and strong policies to protect privacy while allowing sharing of data with physicians, patients, and researchers (The Academy of Medical Sciences, 2013).

All health care systems of the world currently struggle to create electronic health records that will allow physicians anywhere to have access to basic clinical data on patients. However, the new era of personalized medicine will generate literally billions of data points for each patient. This volume of data will create three major challenges. The first concerns the infrastructure to generate the data and to store them securely and confidentially but yet allow easy access to qualified caregivers. The second challenge will be the need to create sophisticated analytical tools to mine the data for the key information that will inform patients and caregivers about the nature of their illness and suggestions for future studies and even possible treatments. The third challenge will be to develop regulatory frameworks that allow sharing of patient data across jurisdictional barriers. At present, regulations and technical challenges make it difficult to even share data between hospitals. But the future will require data sharing between regions within a country and between countries.

Health research will also require access to large international data sets in order to identify critical correlations between biological biomarkers, clinical symptoms, behavior traits, and

environmental exposures. As stratification becomes more precise, it will be difficult for a single institution to have enough patients to completely characterize subgroups. Some recent studies in neuropsychiatric diseases have involved analyses of tens of thousands of patients.

Complexity of Delivery of Health Care by Nontraditional Means

The benefits of the personalized approach to health care require the interaction and collaboration of large groups of professionals and other support staff, as well as active participation by patients in managing their health care. These interactions will require new administrative and governance structures to maintain both quality and smooth operation of these complex systems. It is very likely that health care will involve the incorporation of nontraditional (i.e., nonmedical) caregivers, such behavioral scientists, personal trainers, bioinformaticians, and so on, into the care team. In addition, it will likely become impossible for a single institution to have all the types of skills needed to deliver personalized care; multi-institutional care teams create many problems in coordination and governance.

Consequences of Predicting Outcomes

One of the challenges for patients in the increasing use of genetic profiles to predict disease is to decide what to do with this information. Prediction creates many problems for patients and caregivers. For some diseases such as hereditary breast cancer, where having a genetic mutation greatly increases the risk of breast cancer, women can choose more frequent screening to detect early, more easily treatable cancer, or they can choose more radical approaches such as preventive mastectomy. The decisions to pursue preventive strategies will require input from the individuals involved as well as other experts and support persons. Other diseases such as Huntington's disease have no known preventive strategies. In these instances, individuals obtaining genetic profiles will need to specify before the screen whether or not they wish to receive information about risks of incurable diseases.

In other instances, how to deal with prediction becomes highly stressful and difficult. Individuals receiving a prediction of increased susceptibility to diabetes or heart disease can choose lifestyle modifications that can reduce the risk. However, at present, both the prediction and the lifestyle changes are subjected to significant variation. Thus, a genetic profile may indicate a 30% increase in risk of heart disease. However, development of heart disease is a complex process involving many variables, only one of which is genetic, and an individual with a high genetic risk may not get heart disease. In addition, because of the variability in factors influencing the onset of a disease, the recommended behavior modification may not prevent the disease. For these reasons, it will become increasingly necessary to provide expert support to individuals who seek to use these genetic profiles to improve their health.

Another area where prediction of outcome creates challenges for patients and caregivers is in the use of genetic profiles to predict which patients will respond to a specific course of therapy. In some of the examples described above, the predictions are highly reliable and not challenging to implement. Thus, patients with lung cancer will only receive crizotinib if their tumors contain an alteration in the ALK-1 gene. There are much data showing that the majority of patients lack this change and do not benefit from the drug (Gandhi and Janne, 2012).

A more challenging situation exists for breast cancer, where a genetic profiling kit is being used to predict the chance of recurrent metastatic breast cancer in women who initially had localized cancer (node-negative). The commercial Oncotype DX test measures the expression of 21 genes in the patient's tumor. Based on the results, patients are categorized into low, intermediate, or high risk. Several clinical trials have shown that although some women in the low or intermediate risk develop metastatic disease, there is no benefit in receiving chemotherapy as a preventive strategy (Medical Advisory Secretariat, 2010). In contrast, women in the high-risk group have 40% chance of developing metastatic cancer if they receive standard therapy, but the risk reduces to 12% if women receive extra chemotherapy in addition to standard therapy. While the test provides clear benefit to some women, it is important to note that even in the high-risk group 60% of women will do well with standard therapy and do not benefit from the additional chemotherapy.

Need New Systems for Introducing Innovations in Health Care

The magnitude of changes on the horizon for health care systems is causing great angst among the policy- and decision-makers in these systems (Downing, 2009). As described above, the move to personalized health care will require radical change in health care systems, but no one has a blueprint for the change. In fact, it is likely impossible to establish a formula for change of this magnitude, as it is unlikely that one size will fit all. Health care is very contextually sensitive and is greatly influenced by history, culture, and social pressures.

The Basque Country in Spain has developed a model, which others might emulate. The Ministry of Health in the Basque Country has established the Basque Foundation for Health Innovation and Research "to promote innovation and research in the Basque Health Service, Osakidetza, to achieve continuous development and improvement in the capacity of the service to care for the health of the people in the region." The Foundation has established several programs to foster innovation in health care by promoting pilot studies on the system to identify innovations that bring great health benefit in a cost-effective manner (e.g., Orueta et al., 2014).

Roles for Behavioral Scientists

As mentioned several times above, behavioral scientists need to help shape the evolving new health care systems that will focus on individualized therapy. In the sections below, we will describe a few areas that offer unique opportunities for behavioral scientists to contribute both to research and innovation in new health care systems.

The future will see patients taking increased responsibility for their own health care. For example, the increasing availability of commercially available diagnostic kits (glucose level, pregnancy, HIV, etc.) allows individuals to self diagnose and decide their own course of treatment. There will be increasing numbers of nontraditional (i.e., nonmedical) health care professionals, and health care will involve teams of caregivers

working collaboratively with patients to deliver increasingly complex, but more effective, interventions.

Interventions Requiring Behavior Change

Some of the greatest opportunities and challenges for behavioral scientists lie in developing new strategies for modifying behaviors for health benefits. Everyone accepts that behavior is a mixture of nature and nurture with important influences coming from genetic, environmental, psychological, and social factors. Recent work has also shown that epigenetic factors such as methylation likely play important roles in developing behavioral patterns (Champagne, 2010). A major challenge will involve dealing with the complexity, variability, and plasticity of epigenetic changes over time. Investigating these interactions will require large data sets on genetic composition of patients and family members, a social history of the patient, and extensive health records over time. One can envisage complex, multidisciplinary teams that will analyze these large data sets and optimize individual plans for patients to achieve a desired behavior change such as smoking cessation, loss of weight, or increased fitness.

For example, psychologists will shape smoking cessation programs based on the knowledge of the nicotine receptors that influence the strength of the addiction; recent studies show the strong correlation between the genetic type of nicotinic acid receptor and response to cessation therapy (Chen et al., 2012). The increased knowledge of the role of genetics in behavior is already sparking many new research topics, and these opportunities will only increase if knowledge of the links between genetics and behavior increases (Munafò et al., 2004; Schnoll et al., 2007).

This optimization of individual plans for behavior change has seen increased attention in the literature over the recent years, and has been referred to as 'tailoring,' i.e., "any combination of strategies and information intended to reach one specific person, based on characteristics that are unique to that person, related to the outcome of interest, and derived from an individual assessment" (Kreuter et al., 2013: p. 277). As opposed to targeted interventions, which are designed to be effective with all segments of the population, tailored communications are uniquely individualized to one person. Results from a *meta*-analysis including 57 studies (Noar et al., 2007) suggest that tailored health messages are effective and identify numerous factors that moderate the effects of tailoring. The strongest (print) tailored health message interventions were those that intervened on preventive or screening behaviors, generated pamphlets, newsletters, or magazines (including visual elements), utilized more than one intervention contact, recruited participants from households rather than clinics or health centers (probably due to differences in socioeconomic status), and involved psychological concepts such as attitudes, self-efficacy, stage of change, and social support.

Even though the studies included in this *meta*-analysis involved those using mainly health behavior information, it is clear that the case for tailoring health behavior interventions becomes even more convincing (and probably successful) when it includes genetic information. Nevertheless, as of now, no genotype-tailored interventions, i.e., interventions matched to an individual's specific genetic variation, have been evaluated in terms of increasing adherence to or favorable outcomes of behavior change interventions. One small study (Arkadianos et al., 2007) investigated whether the inclusion of genetic information to personalize a patient's diet (nutrigenetics) could improve long-term weight management. The results suggest that the addition of nutrigenetically tailored diets leads to better adherence, longer-term BMI reduction, and improvements in blood glucose levels. Although this study had a number of methodological limitations (e.g., nonrandomized design), it provides a first example of research that should be followed up in the future.

As this example shows, the inclusion of genetic information in personalized health interventions may increase their efficacy (and effectiveness). Nevertheless, it is also likely that the factors known to reduce adherence in general, e.g., forgetting (retrospective and prospective memory impairments), and perceptual and practical barriers (motivation and beliefs, capacity and resource limitations) will also reduce the efficacy of personalized medicine approaches. In addition to these factors, it needs to be taken into account that patients may need (personalized) treatment of comorbid mental disorders such as depression and anxiety (Prince et al., 2007), which in turn may reduce the effects of the intervention through nonadherence and other behavioral processes. It will be crucial for the success of personalized medicine interventions to develop approaches that consider these psychological factors.

The evidence concerning the use of genetic information to motivate risk-reducing behaviors has been reviewed by McBride and coauthors (McBride et al., 2010). Most research in this area has focused on the effects of information related to rare genetic variants on screening behaviors, in which genetic risk feedback has been demonstrated to be significantly associated with improved screening adherence. Much less is currently known about the effects of information on common genetic variants; however, the limited evidence available suggests that genetic information based on single-gene variants with low-risk probabilities has little impact on behavior. In the case of smoking cessation, for example, findings suggest that genetic risk feedback will not add value to existing smoking cessation programs when (1) very small increases in risk are conveyed, (2) personalized risk feedback is based on a single genetic variant, or (3) smokers have high preexisting levels of motivation to quit.

Change Management

The evolution (revolution) of health care systems will create enormous problems in change management: the recent attempts to implement general health insurance in the United States illustrate this problem (Blank, 2012). Job descriptions will change, and caregivers will have to work in new environments. Patients will have to accept new responsibilities and navigate increasingly complex health care systems. Successful evolution will likely happen best in those systems that effectively consider and plan for all the change management issues that will certainly arise. Because of the complexity and extent of the anticipated changes, change management teams will be essential for the successful introduction of new innovations.

The complexity of the anticipated innovations will also create many opportunities for research on change management. Change management is highly dependent on the context in which the change occurs. Cultural, social, and historical factors can greatly influence the ease or difficulty of implementing a new innovation. A desired outcome of research in change management will be the development of flexible strategies and processes that many can follow to facilitate change in many different situations. A unique feature of the Basque Country program is the recognition that implementation of new innovations may involve different pathways in different areas of the Country.

Creating Teams

The success of personalized medicine will depend greatly on the creation of new multidisciplinary, multi-institutional teams to develop and manage health care. Many of these teams will likely consist of disciplines that do not frequently interact and whose different approaches to problem solving will make interactions difficult. Understanding how to encourage and reward teams will become increasingly important. One challenge that many institutions already face is how to reward and recognize participation in teams. The traditional reward mechanisms tend to recognize only the leaders, and this process will not work in the future.

Risk Perception

Many of the diagnostic tests for personal medicine will give probabilities of various health outcomes. For patients and caregivers to use such information, they must have some understanding of risk and what the numbers actually mean. Scientists have studied risk perception for many years and generally found that most people either underestimate risk or overestimate actual risk. Recent studies have shown that in the United States, only 13% of the people are proficient in numeracy (O'Rourke, 2013), so perhaps it is not surprising that accurate understanding is rare.

Some experts have suggested that absolute risk is an easier concept to understand. Consider the following hypothetical situation. A patient is told that a certain medication has a 50% increased risk of heart attack over the next 5 years. Many patients would be frightened by this number and assume that 50% of people taking the new drug would experience a heart attack. The patients need additional information to interpret this risk. Assume that among 1000 people who are not taking the drug, two will have heart attacks. Among those taking the drug, three will have heart attacks, a 50% increase. The absolute risk is only one extra death per 1000 people taking the drug. This example is a simple case, but illustrates the need to express risk in terms easily understood by patients. Understanding health risks posed by genomic testing will be much more complicated because many factors in an individual profile will influence both the risk and the perception of risk. Clearly the area of risk perception will require new strategies to help individuals understand these new sources of health information.

A quantitative review of studies investigated the effects of communicating DNA-based disease risk estimates on risk-reducing behavior (Marteau et al., 2010). Mindful of the weak evidence of a total of only 14 studies of limited quality, the authors conclude that communicating DNA-based disease risk estimates has little or no effect on smoking and physical activity, but may have a small effect on self-reported diet and on intentions to change behavior.

Largely unexplored are the effects on psychological and behavioral outcomes of risk feedback based on the more realistic scenario in which genetic risk is based on numerous genetic variants. Lastly the evidence reviewed by McBride et al. (McBride et al., 2010) suggests that health literacy will affect the understanding of and engagement with genomic information in ways that diminish its potential to induce health behavior change. This underlines the need for providing expert support to individuals who seek to use these genetic profiles.

It is likely that the categorization of patients will not be deterministic in terms of prognosis. Rather, the diagnostic protocol will provide probabilities in terms of disease risk or response to treatment. In general, patients do not deal well with risk assessment in terms of changing their health behaviors or accepting treatment (e.g., adherence) as a consequence of risk information. This may be due to (nongenetic) risk information often being too general (i.e., not personalized enough) to allow perceived vulnerability to sufficiently develop and, therefore, to increase motivation to change (McBride et al., 2010). Even though the highly personalized nature of genetic information may have an advantage over other risk information for influencing health behaviors, a large body of evidence from the social and behavioral sciences suggests that the perception of threat is not sufficient to motivate behavior change (Bowen et al., 2004). It will, therefore, be important to develop tools and protocols to support patients, their social networks (e.g., families, friends), and caregivers in specific health behavior change intervention programs, and to allow them to understand the treatment options, and most importantly why specific patients may be denied a treatment (Vernon, 1999).

Conclusions

Research in medical and behavioral sciences is leading to increased personalization of treatments based on improved understanding of the genetic, biological, environmental, psychological, and social factors affecting each individual. The need for the health care systems to adopt changes represents a level of unprecedented change and could lead to disruption and dysfunction in health care provision unless a widespread spectrum of expertise helps shape new systems of health care. At present, there is little interaction between the medical and behavioral sciences, and we urge that the groups increase their interaction in order to shape a radical new paradigm of health care that incorporates both medical and behavioral elements of personalization.

Abstract

The anthropology of personhood encompasses the definition and study of three conceptual terms: person, self, and individual. It explores the identity of the individual actor and the relationship between that identity and the symbolic forms and material and moral practices of various sociocultural milieus. Recognizing the *individual* in the *role player*, the anthropologist comes to portray sociocultural milieus as composed of and constituted by a diversity of individual consciousnesses: human actors making a diversity of meaningful worlds by way of a commonality of cultural forms. Recognizing that *any* human individual may exist within any sociocultural role, the anthropologist moves from particular environments of conventional symbolic exchange toward an appreciation of personhood as an issue of moral universality.

The anthropology of personhood encompasses the definition and study of three conceptual terms: person, self, and individual. It is the exploration of the nature of the identity of the individual actor and the relationship between that identity and the symbolic forms and material and moral practices of differing sociocultural milieus.

On neither the meaning nor the implication of these conceptual terms, however, can significant disciplinary consensus be found; a number of writers have addressed definitional issues directly (Harris, 1989; Morris, 1994), but strong disagreements remain. The dissension is perhaps understandable when one considers that what is fundamentally at issue is the nature of individual consciousness and its manifestations – emergence, development, and construal – in different times and places. What is the relationship between 'nature' and 'nurture' in this context? Between consciousness as a biological given and as a sociocultural construct? Between consciousness as privately experienced and as publicly validated? Between consciousness as uniquely embodied and as collectively elicited and known?

The position taken in this article is that an anthropological study of personhood must be careful to distinguish between what may be termed 'individualism' and 'individuality': that is, between the conventional conceptualization of individual actors in particular settings ('individualism'), on the one hand, and the universal condition of our human-individual embodiment ('individuality'), on the other. Much of the conceptual difficulty the discipline has experienced arises from a conflating of these two, a confusion that goes back to Durkheim's formulation of a 'social' as against a 'psychological' science.

Social Structure and System

The Durkheimian Individual

Durkheim conceived of human beings as *homo duplex*; on one side there was the biological and personal (comprising the individual body, with its material senses and appetites) and on the other side the social and moral (the conceptual and conscientious). The individual thus led a double existence: one rooted in the physical organism and one (morally, intellectually, and spiritually superior) in a social organism of collectively and uniformly held ideas and practices. Between the two there was ongoing antagonism and tension, but through inculcation into a public language and culture, humankind was capable of rising above mean (animal) 'individuality' and becoming part of a collective consciousness and conscience in which the (sacred) traditions of a society were enshrined. If individuals were indeed conscious of themselves as individuals, then this was equally a product of their socialization in a collective consciousness; 'individualism' was a social product, like all moralities and all religions.

From Durkheim's (structuralist) descendants, a collectivist narrative was elaborated that conceptually subsumed the individual actor within sociocultural contexts. Marcel Mauss (1985) took it upon himself to detail how experience was constituted by cultural categories and thus how society exerted its force on the physiological individual. He outlined a purported evolution in individual identity that could be tied to the particular forms of social structuration. First comes the Tribal stage of *personnage*, in which individuals are conceived of as ephemeral bearers of a fixed stock of names, roles, and souls in clan possession; having no existence independent of the clan, individuals possess no inner conscience. Next comes the Classical stage of *persona*, in which individuals are conceived of as independent and autonomous citizens of a state; they are responsible, legal persons but still they possess no inner life or identity beyond the civic. With the rise of Christianity comes the stage of *personne*; conceived of as indivisible and rational, possessing a conscience, indeed, a unique sacred soul, the individual now serves as the foundation of all political, economic, and legal institutions. Finally comes the peculiar Western stage of *moi*, the individual as a 'self,' with self-interest and self-knowledge, as validated by modern institutions of psychological science.

Beginning with the assumption that sociocultural holism represents the paradigmatic form of human experience, Louis Dumont (1986) set out to plot more precisely the origination and progression of the singular Western idea of the autonomous individual as bearer of supreme moral value by comparing it with the Oriental 'archetype.' The Christian *personne*, he suggests, is reminiscent of the Hindu figure of the 'world renouncer,' someone who seeks ultimate truth by

 http://dx.doi.org/10.1016/B978-0-08-097086-8.12128-2

forgoing the world in favor of his own individual spiritual progress. In the world renouncer, one finds a Western-like individualist for whom society has lost its absolute reality and who, despite the constraining interdependence Indian society ubiquitously imposes on its members, has become self-conscious and self-sufficient. The evolution of the Western individual and the 'substitution' of self for society as absolute value marks the triumph of a (Christian) religious ideology in which worldly renunciation becomes the collective norm. Christ's teaching that a human being possesses a soul that absolutely transcends the world of social institutions and powers (a soul that is absolutely individual in relation to God and meets others' souls only in God) engenders a community of 'outworldly' individuals who meet on Earth but have their hearts in heaven. Nonetheless, Dumont concludes, the evolution need not end there; in the wake of such essentialist movements as nationalism, multiculturalism, fascism, and Islamic fundamentalism, the cultural future of individualism is, to say the least, unpredictable.

Characterizing the above, the 'Durkheimian' line of thought, in short, is the idea that the individual actor in Western society is the result of a recent and exceptional historicocultural development. The concept of 'the individual' and its moral and social significance is absent elsewhere, with no a priori differentiation being made between individual and role, between self and society.

Versed in this paradigm, moreover, it is not surprising that in much anthropological reportage about the person, one finds a denial of individualism and little discussion of individuality. Inasmuch as 'the individual' exists, it is as a particular manifestation of 'the person'; individuals become collective constructs within the contexts of specific cultural ideologies and social practices, their psyches emanations of certain pre-given and prestructured life-worlds of socialization. It is not individual human beings who are seen to possess features and characters – such as uniqueness or self-awareness or loneliness – so much as the working parts of the complex social systems of which they are representative components and conduits.

For instance, Marilyn Strathern (1988) describes Melanesian personhood not in terms of individuals – distinct actors possessing discrete emotions, awareness, and agency – but in terms of 'dividuals,' beings constituted by properties, goods, and substances that are exchanged with others in an ongoing manner. The Gahuku-Gama of New Guinea, Kenneth Read (1955) elaborates, are conscious of themselves only as members of common categories of relationships: rather than, say, 'friendships' between unique individuals there are only relationships between socially defined positions. Similarly, Fred Myers (1986) records Australian Aboriginal 'emotions' not as pertaining to deep psychological experiences of the individual but as cultural evaluations of people and circumstances that persons must make in order to live in fluxional social settings. Rane Willerslev (2007) describes how, for the Yukaghirs of Siberia, humans, animals, and spirits are mimetic doubles of one another, with the consequence that in maintaining their identity 'individuals' also transcend difference; here are human beings who inhabit a betwixt-and-between state in which their souls are both their own and reincarnated others, human and animal. Finally, Geertz (1973, p. 360 ff) relativizes Western conceptions of the autonomous individual by emphasizing the collective role playing fundamental to the Balinese habitus of the person. Culture, Geertz suggests, translates into symbolic 'control mechanisms' by which the breadth and indeterminate qualities of actors' potential social lives are programmatically reduced to the specificity and narrowness of their actual ones.

In sum, a Durkheim-inspired anthropology of personhood has eventuated in comparative inquiries into the diversity of sociocultural conceptions of the human individual, how these conceptions connect with other sociocultural 'institutions' (family, law, exchange), and how these different ways of conceptualizing determine differences in experience. 'Personhood,' in this view, amounts to "those culturally constituted and socially conferred attributes, capacities and signs that mark a moral career and its jural entitlements in a particular society" (Poole, 1998, p. 842). 'Selfhood' refers to a human being as a locus of experience, as this experience is culturally allocated and defined – most often as relational, socially embedded, and sociocentric. The term 'Individual' encompasses an actor's uniqueness to the (rare) extent that the latter is realized in certain collectively structured life-worlds.

The Non-Durkheimian Individual

There have been exceptions to the Durkheimian line, nevertheless: ethnographies and analyses that recognize the individual to be always 'the anthropological concrete' (Auge, 1995, p. 20) from which social analysis must begin. Not only is it always individuals whom the anthropologist meets as informants (Miller, 2009), then, but "any history or description of a social situation is an exercise of psychological knowledge" (Simmel, 1971, p. 32). It is simply not good enough for social science to claim a social-factual priority (ontological, developmental, historical) of the social structural so as to assert an overwriting (causing and conditioning) of individual experience.

For instance, tracing the 'origins of English individualism,' Alan Macfarlane (1978) sets out specifically to refute those theorists who would see individualism as a recent sociocultural development – whether epiphenomenal upon religious or Renaissance or Enlightenment or capitalistic or industrialistic thinking. For "the majority of ordinary people in England from at least the thirteenth century were rampant individualists," Macfarlane writes (1978, p. 163), "highly mobile both geographically and socially, economically "rational," market-oriented and acquisitive, ego-centred in kinship and social life." In New Guinea, meanwhile, Kenelm Burridge (1979) describes how most people are 'individuals' and 'persons' in different respects and at different times, where the word *persons* may be understood to mean those who realize given sociocultural categories prescribed by traditional morality and the social order, whereas *individuals* are those who use their perception and intuition to create anew. If persons are products of current sociocultural conditions, then individuals exist in spite of them. Each 'spatially bounded organism' – or human being – is able to switch between these two modalities; Burridge concludes that individuality represents an existential imperative that pre-exists culture. This also accords with Unni Wikan's (1990) reappraisal of the Balinese, where the institution of cultural norms of

personal composure, grace, and placidity do not obviate the individual emotional effort that is recognized as being necessary to effect and sustain their appearance.

An emphasis on individual actors, their personal experience and agency, has similarly found expression in anthropological theorists of consciousness (from Gregory Bateson and Anthony Wallace onward), in the Transactionalism with which Fredrik Barth (also F.G. Bailey and Robert Paine) developed Edmund Leach's insights into instinctually 'interested' individuals, in the work of network analysts (such as John Barnes and Ulf Hannerz), and in the burgeoning of studies within interpretive or symbolic-interactionist anthropology more generally, which focus on the constructions of experience made by particular individuals in interaction. These accord more with Weberian sentiments that collectivities must be approached solely as the resultants and modes of organization of the particular acts of individual persons because it is they who remain the upper limit and the sole carriers of meaningful conduct.

Existence and Experience

Form and Meaning

Structuralist and poststructuralist discourses still denigrate anthropological sensitivity of the kind discussed immediately above as 'methodological individualism': as an erroneous couching of explanation in terms of individuals' characteristics, behaviors, and interests, such that the foundational conditions of sociocultural reality are obscured. The centerground of anthropology, it may be true to say, remains the preserve of 'methodological collectivism,' positing social phenomena as determined by factors that bypass individual rationality, hence envisaging cultural development quite independent of individual consciousness. There is a continuing insistence, in other words, that the distinction between the individual and the societal is specific to the West and must be collapsed in favor of the latter – or at least of 'social relations' – for anthropology persuasively to encounter cultural others.

On the other hand, there is a growing insistence that it is a peculiar ethnocentrism for anthropologists to fail to allow, in the 'others' we study, the personal complexity we recognize in ourselves, as both individuals and persons, role players and rebels, conventional and creative beings. The anthropology that has sought most deliberately to keep this truth in view may be termed 'existential' or 'phenomenological,' after the philosophical traditions associated with such writers as Kierkegaard, Nietzsche, Husserl, and Sartre (Jackson, 2005). It sets out with very different tenets and intentions from the 'sociological' orientation toward social structures and systems predominant above, privileging instead individual existence and experience and their moral demands.

To become human is to become individual, Geertz admits (1973, p. 52), even though we become individual in environments of sociocultural forms and patterns in whose terms we give order, direction, and point to our lives. The important question this raises is the precise relationship between sociocultural forms and the individual lives lived by them. Becoming human and individual in an environment of common sociocultural forms need not eventuate in becoming 'the same' as others or even necessarily comparable, nor in becoming according to a deterministic or directly influenced fashion, nor in becoming only once-and-for-all. For in this human becoming, energy, agency, intention, and interpretation can be seen to remain properties of embodied individual subjects. It is human beings as individual actors who are responsible for the animation, deployment, and ongoing development of systems of symbolic forms (Rapport, 1993). Forms may possess an environmental objectivity, but they come to be imbued with subjective significance and deployed in contexts whose depths of subtle distinction are likely to be more private than public.

Individualism and Individuality

An intrinsic dichotomy between individual and world is often eschewed as a peculiarity of the 'Western' sociocultural milieu, as we have heard, and hence as methodologically and analytically inapplicable. This is hardly defensible. Human beings may be socioculturally situated, but they are also, always, interpretively independent – responsible for a 'personalization' of the world – and inexorably and inevitably (by) themselves. It is not good enough simply to say that only Western culture valorizes the concept of the individual – as 'individualism' – and therefore only in Western society do individuals act distinctively with 'individuality.' For although the former might be said to describe a particular sociocultural form of behavior (the pursuit of self-distinguishment), the latter concerns a condition that is a human universal: by virtue of a unique, embodied consciousness, each of us perforce engages with the world as other and is possessed of distinct perspectives upon it.

Individualism, more precisely, pertains to a specific historicocultural conceptualization of the person that includes such notions as the ultimate value and dignity of human individuals; their moral and intellectual autonomy; their rationality and self-knowledge; their spirituality; their right to privacy, self-sovereignty, and self-development; and their voluntary contracts with a society, market, and polity. *Individuality*, by contrast, refers to that unique awareness, and awareness of awareness, that is the mark of human embodiment. It is the universal nature of existence that human beings engage with others by virtue of discrete sense-making apparatuses (nervous systems and brains); they possess discrete centers of perceptual activity in discrete bodies. Furthermore, the human body (in particular, the brain) gives rise to knowledge of the world, to a perspective upon the world, that is inherently individual. Human beings come to know themselves in the world by way of cognitions and perceptions, thoughts, feelings, and imaginings that are unique to them (Edelman, 1992).

There is an individuality intrinsic to human consciousness and also to human agency. For it is in terms of his or her perceptions that an individual comes to act, each individual becoming a discrete center of motivation and intention, of 'existential power' (Rapport, 2003). Not only is the individual's being-in-the-world universally mediated by very particular interpretative prisms that distance him or her from it, but while intrinsically 'of the world,' the individual inexorably comes to

know the world and act toward it, as 'other.' Individuals experience and interpret (and experience themselves interpreting) and therefore, they are.

An individuality of consciousness and agency is existent – an empirical truth – whatever the provenance of individualism as a cultural norm. Individuality is the human a priori, the physical–psychical basis on which all human knowledge of the world, all creativity within it, and all activity upon it, rests (including the creation and representation of sociocultural milieus). Individuality remains consequential, that is, whether or not individual consciousness is an item of collective discourse, whether or not individual reflection is publicly eschewed, and whether or not individual distinctiveness is disparaged through the institutionalization of a fund of common behaviors (concerning, for instance, notions of the person). The experience of self is essentially distinct from sociocultural representations of self (Spiro, 1993). Finally, an existential anthropology of personhood can hope to 'decolonize' (Cohen, 1994) the individual human subject, both from overdetermining cultural conditions and overweening social institutions (discourse, language-game, collective representation, social relationship, habitus, praxis) and from holistically minded social-scientific commentators. Recalling Simmel, the anthropologist offers an account both of the individual agency that brings sociocultural milieus to life alongside the common sociocultural forms and practices by which individuals coordinate their activities within these milieus (Amit and Dyck, 2006).

The interface between form and meaning is ambiguous, but recognizing the distinction is vital both epistemologically and ethically. Recognizing the individual within the role player, the anthropologist portrays sociocultural milieus as being composed of and constituted by a diversity of individual consciousnesses – human actors making a diversity of meaningful worlds by way of a commonality of cultural forms. Recognizing that *any* human individual may exist within *any* sociocultural role, the anthropologist moves from particular environments of conventional symbolic exchange toward an appreciation of personhood as an issue of moral universality (Rapport, 2012). The individual actor is warranted a space to inhabit worldviews and life-projects of his or her own making and esteeming and in distinction from the conventional conceptualizations of personhood.

Abstract

Personnel selection is a very important component of human resource management toward creating and sustaining effective organizations. In this article, we argue that organizations can best build a successful workforce by using systematic selection procedures that employ approaches and methods from the field of industrial and organizational psychology. Thus, we describe job analysis to identify the performance requirements of jobs, as well as the knowledge, skills, and other personal characteristics necessary to be successful in each of these target jobs. This, in turn, drives the choice of assessments to evaluate applicants most likely to be effective employees, and we describe these kinds of assessments.

When an organization has a certain number of positions to fill and more applicants than positions, some type of selection process is necessary to place applicants in the jobs. Of course, this can be handled quite casually by conducting unstructured interviews and selecting people who seem most qualified for each position. Or, we can take a more systematic approach by conducting a job analysis for each of the target jobs, choosing or developing assessments to evaluate each applicant's predicted performance on one of these jobs, and then selecting an applicant who performs very well on the assessments and is thus presumably well qualified for the position. This more systematic approach typically involves an additional step in which the validity of the assessment process is evaluated to ensure the process is selecting individuals who do in fact perform effectively on the job.

The following sections discuss this more systematic approach to personnel selection. We first describe basic job analysis procedures and then one result of these procedures, the development of performance requirements or criteria. These criteria can inform the choice of predictors. Measurement of these criteria can also help in the predictor validation process to be described toward the end of this article.

Next, we present the variety of types of tests (e.g., personality, vocational interests) and other predictors (e.g., structured interviews). And finally, we discuss the validation process to evaluate the effectiveness of the predictors' identification of applicants who turn out to be high-performing employees.

Job and Work Analyses

Job analysis is a process of systematic inquiry aimed at discovering and documenting the essential nature of work (Brannick et al., 2007). Job analysis can be used for a variety of purposes including personnel selection, training, job design, and compensation. For personnel selection purposes, job analysis is concerned with identifying work behaviors and the knowledge, skills, abilities, and other characteristics (KSAOs) needed to perform those work behaviors. On the predictor side, job analysis is concerned with identifying the KSAOs and developing or using existing tests to measure them. On the criterion side, job analysis involves identifying job performance measures that tap the important performance requirements of the job and inform on KSAOs needed to perform effectively on the job.

Criterion Development and Measurement

It is now widely accepted that job performance is a multidimensional construct (Sackett and Lievens, 2008). The most commonly studied dimensions include task performance, citizenship performance, adaptive performance, and counterproductive work behaviors.

Task Performance

Task performance refers to the technical proficiency part of job performance (Borman et al., 2010). Task performance can be measured objectively or subjectively. Although objective measures of job performance look appealing, for most jobs they only tap into part of the criterion space. Objective criteria include production rates, sales, work samples, and job knowledge tests. Subjective criteria are the typical performance ratings usually provided by a supervisor. Performance ratings are the most commonly used criterion measures in industrial and organizational psychology research and practice.

At least six taxonomies examining the dimensionality of task performance have been proposed (e.g., Borman and Brush, 1993; Borman et al., 1994; Hunt, 1996). Borman et al. (2010) summarized the common content across the six taxonomies. All of the taxonomies involve content related to communication and productivity/proficiency. Personal qualities and skills are reflected in five taxonomies. Problem solving, organizing/planning, and leadership/supervision are represented in four taxonomies. Accordingly, these are some of the exemplars we expect to see representing task performance dimensions such as those just identified. Task performance is usually measured by asking supervisors to rate their subordinates on various behaviors relevant for the job. Several rating formats are

available including Behaviorally Anchored Rating Scales (Smith and Kendall, 1963), Behavior Summary Scales (Borman, 1979), Behavior Observation Scales (Latham and Wexley, 1981), and Computer Adaptive Rating Scales (Borman et al., 2001). To improve the quality of the ratings, raters can be trained using rater error training (which shows raters the common psychometric and perceptual errors commonly made) and frame-of-reference training (which familiarizes raters with the content of each performance dimension).

Citizenship Performance

In addition to task performance, employees engage in activities that support the broader work environment. These activities constitute the contextual or citizenship performance domain (Borman and Motowidlo, 1993). Since the introduction of organizational citizenship behavior (OCB) in the early 1980s (e.g., Smith et al., 1983), researchers proposed several taxonomies and Podsakoff et al. (2000) identified more than 30 unique dimensions for OCB or contextual performance. Coleman and Borman (2000) integrated the various dimensions into a three-dimensional interpretation consisting of personal support, organizational support, and conscientious initiative. A general and commonly used distinction is made between citizenship performance activities targeted at individuals and performance activities targeted at the organization. Citizenship performance can be measured using supervisor ratings; however, peer and self-ratings are also commonly used, with some authors (e.g., Allen et al., 2000) suggesting that peers are the best source for the ratings.

Adaptive Performance

Adaptive performance refers to behaviors that meet the demands of a new or changed situation or event. Pulakos et al. (2000) developed an eight-dimension taxonomy of adaptive performance (e.g., solving problems creatively, learning new tasks and procedures). Adaptive performance is distinct from task and citizenship performance (Hesketh et al., 1996). Adaptive performance is predicted by cognitive ability, self-efficacy, and achievement motivation (Chen et al., 2005; Pulakos et al., 2000, 2002). Jobs differ in their adaptability requirements (Pulakos et al., 2000) with most of the adaptive performance research being conducted on military samples.

Counterproductive Work Behaviors

Counterproductive work behaviors (CWB) are behaviors that are intended to harm the organization and its stakeholders (Spector and Fox, 2005). The most common CWB typology distinguishes between CWB targeted at the organization and CWB targeted at the individuals (Robinson and Bennett, 1995). Spector et al. (2006) proposed a more refined taxonomy consisting of five dimensions: abuse, production deviance, sabotage, theft, and withdrawal. Due to their nature (CWB are behaviors most likely performed without observers), CWB are primarily assessed using self-reports. Alternative sources for the assessment of CWB include coworker reports (Fox et al., 2007) or objective indicators retrieved from organizational records (e.g., Ilie et al., 2012).

These and other criterion measures are used to evaluate the validity of predictors in a personnel selection context. A wide variety of tests and other predictors have been used to aid in selecting employees.

Types of Predictors

Cognitive Ability

Cognitive ability is defined as a general mental capability involving reasoning, problem solving, planning, abstract thinking, complex idea comprehension, and learning from experience (Gottfredson, 1997). Probably the most comprehensive taxonomy for cognitive abilities is the three strata model derived by Carroll (1993). The first stratum consists of specific and narrow abilities, the second includes group factors and broad abilities, and the third stratum is general intelligence or g (Ones et al., 2012).

Cognitive ability is widely considered the best predictor of job performance (Schmidt and Hunter, 1998). *Meta*-analytic reviews and primary studies link cognitive ability to job performance in both United States and European countries (Ispas et al., 2010; Ones et al., 2012). The predictive validity of cognitive ability depends on the complexity of the job with the strongest validity coefficients observed for highly complex jobs (Ones et al., 2012). Cognitive ability impacts job performance through job knowledge acquisition (Borman et al., 1991, 1993); high cognitive ability individuals are better equipped to acquire the knowledge needed to perform their jobs at the highest levels. The *meta*-analytic estimate of the general cognitive ability–overall job performance relationship is 0.51.

A small number of studies examined citizenship performance or CWB as criteria. Alonso et al. (2008) *meta*-analyzed 13 studies linking cognitive ability and citizenship performance and found an uncorrected correlation of 0.05. When using CWB as the criterion, the results show validity coefficients around −0.15 to −0.20 (Ones et al., 2012). Dilchert et al. (2007) reported a corrected correlation of −0.33 between cognitive ability and objectively measured CWB.

Personality

Until the early 1990s, the general attitude in the field of industrial and organizational psychology was that personality is not an important predictor of job performance. The emergence of the Five Factor Model (FFM) of personality and the publication of several *meta*-analytic reviews (e.g., Barrick and Mount, 1991; Tett et al., 1991) led to a renewed interest in personality in personnel selection. According to the FFM, personality can be organized into five major domains: emotional stability/neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness. The FFM personality domain has been linked with all of the performance domains: task, citizenship, adaptive, and CWB.

The FFM traits most consistently related to task performance across jobs are conscientiousness and emotional stability (Hurtz and Donovan, 2000; Barrick et al., 2001). Contextualized personality measures (created when scale items include 'at

work' to specify the intended context for the item rather than at home or in general, for example) show a higher predictive validity compared with noncontextualized measures (Shaffer and Postlethwaite, 2012).

For predicting citizenship performance, early *meta*-analyses showed that the FFM traits of conscientiousness and agreeableness had the strongest correlations (Borman et al., 2001). However, the most recent *meta*-analysis (Chiaburu et al., 2011) found that conscientiousness, agreeableness, and openness are the best predictors, and even the FFM traits of extraversion and emotional stability are important by showing incremental validity over conscientiousness and agreeableness. Overall, the FFM shows stronger associations with citizenship performance (multiple $R = 0.28$) than with task performance (multiple $R = 0.19$; Chiaburu et al., 2011).

For CWB, conscientiousness, agreeableness, and emotional stability emerge as the most consistent predictors (Berry et al., 2007; Dalal, 2005). Conscientiousness is more strongly related to CWB targeted at the organization (−0.34) than CWB targeted at individuals (−0.19), whereas Agreeableness shows the opposite pattern (−0.36 for individual CWB and −0.25 for organizational CWB). Emotional stability shows similar relationships with both interpersonal CWB (−0.20) and organizational CWB (−0.19).

In addition to the FFM domains, research has also examined the predictive validity of the facets that constitute the domains (Judge et al., 2013). The achievement striving facet of conscientiousness emerged as the best predictor with an estimated corrected correlation of 0.20 for task performance and 0.29 for citizenship performance.

Although the validities of personality tests have been criticized as being small (e.g., Morgeson et al., 2007), personality has incremental validity over cognitive ability (Schmidt and Hunter, 1998) and allows organizations to achieve diversity goals, that is, hiring more qualified minorities (Hough et al., 2001). Additionally, the validities of personality are larger when using all the FFM traits together (Barrick and Mount, 2012).

Several investigations also showed that the relationship between personality and job performance depends on the context. Meyer et al. (2009), in a *meta*-analytic review, found that the relationship between conscientiousness and job performance was stronger in weak situations (situations low in constraints, e.g., more autonomous). Additionally, some studies found evidence for a curvilinear effect of personality. For example, Grant (2013), in examining the relationship between extraversion and sales performance, found that the most successful employees in terms of sales were 'ambiverts' – those with average levels of extraversion.

In addition to the FFM of personality, several other traits have been linked to job performance. Proactive personality has been related to both task and citizenship performance (Greguras and Diefendorff, 2010). In some cases, non-FFM traits have shown stronger links with performance outcomes. One such example is trait anger which shows stronger links with CWB than any of the FFM traits (Herschovis et al., 2007; Ilie et al., 2012).

Although personality for selection purposes is primarily assessed using self-report inventories, research suggests that other reports (e.g., coworkers) can be more valid predictors of job performance (Connelly and Ones, 2010; Oh et al., 2011). Using other reports can alleviate some of the concerns such as applicant faking raised against the use of personality assessments for personnel selection.

Vocational Interests

Vocational interests are noncognitive constructs defined as relatively stable individual preferences for certain types of work (Harmon et al., 1994). An early *meta*-analysis (Hunter and Hunter, 1984) ranked interests second to last of 11 predictors relative to their predictive potential (only age was less predictive) with a mean validity of 0.10. However, the Hunter and Hunter (1984) *meta*-analysis was based on only three studies. Van Iddekinge et al. (2011a) conducted an updated *meta*-analysis across 74 studies and found mean validities of 0.14 against job performance, 0.26 for training performance, –0.19 for turnover intentions, and −0.15 for actual turnover. Furthermore, in a primary study, Van Iddekinge et al. (2011b) found that vocational interests show incremental validity over cognitive ability and personality for predicting job performance factors. Another line of research focused on using a different conceptualization of vocational interests based on profile coefficients. Following this approach, Nye et al. (2012) found even higher predictive validity ($r = 0.36$) between a congruence index and task performance. In a primary study, Iliescu et al. (in press) found that the congruence index shows incremental validity over personality for the prediction of CWB. Taken together, results of these studies should lead to a reassessment of the role vocational interests can play in personnel selection.

Emotional Intelligence

Emotional intelligence (EI) refers to the mental processes involved in recognizing, using, understanding, and managing one's own and others' emotional states to solve problems and regulate behavior (Mayer and Salovey, 1997; Salovey and Mayer, 1990). There are two major conceptualizations of EI: ability-based EI and trait-based EI (Lievens and Chan, 2010). EI can be measured using self-reports (where the respondents indicate their agreement with descriptive statements, similar to personality tests), and ability-based tests that ask questions about emotions and have right and wrong answers. The link between EI and job performance has been examined in two recent *meta*-analytic investigations (Joseph and Newman, 2010; O'Boyle et al., 2010). In both *meta*-analyses, EI was found to predict job performance. Furthermore, EI showed incremental validity over cognitive ability and personality (O'Boyle et al., 2010), particularly for jobs high in emotional labor, that is, requiring effort to get along with others (Joseph and Newman, 2010). More recently, a primary investigation by Iliescu et al. (2012) found that an ability-based test of EI showed incremental validity over cognitive ability and FFM for jobs where social interactions are important (such as customer service and managerial jobs) and linked CEO EI to institutional performance.

Interviews

Unlike cognitive ability, personality, interests, or EI, interviews are a method not a construct (Arthur and Villado, 2008). Interviews are considered the most commonly used method for

personnel selection in all setting (Ryan et al., 1999). Huffcutt et al. (2001) examined the constructs assessed by employment interviews. They found that 35% of the questions measured personality characteristics, 26% measured social skills, 16% mental ability, 10% knowledge and skills, 4% interests and preferences, and 3% organizational fit.

An important factor that can impact the outcomes of employment interviews is their structure. Structured interviews are more valid on average in *meta*-analyses than unstructured interviews ($r = 0.51$ vs 0.38).

Validation of Predictors

Recall that in order to demonstrate the usefulness of our predictors in a performance selection context, we often empirically validate the relationship between scores on the predictors associated with applicants or job incumbents and their criterion scores assessing their job performance. A significant correlation indicates the predictors are useful in the selection process.

Until fairly recently, the process of establishing validity was conceptualized as consisting of three approaches: content validation, criterion-related validation, and construct validation. Content validation is focused on establishing that the test items are representative of the behaviors performed on the job. Criterion validation is about establishing a link between test items and the performance domain, as we have been highlighting. Construct validation is concerned with establishing that a psychological construct has meaning for job performance.

Following the publication of the most recent Standards for Educational and Psychological Tests (1999), validity is now seen as a unitary concept that requires several sources of evidence. The first source of evidence is concerned with the relationship between the predictors and other related variables. This involves convergent validity evidence (relating the predictor with other tests measuring the same construct) and discriminant validity evidence (relating the predictor with other constructs not expected to be related to the target construct). For personnel selection purposes this refers mostly to criterion-related validity evidence. (Are test scores on the predictor related to job performance measures?) Finally, we should also examine the consequences of using tests for making decisions. For personnel selection, this refers to examining whether the use of tests results in disproportionate hiring of groups (based on age, sex, race, disability level, etc.). This is usually accomplished by assessing subgroup differences in mean predictor scores.

The Society for Industrial and Organizational Psychology published a set of Principles for the Validation and Use of Personnel Selection Procedures (2003). The purpose of the principles is to "established scientific findings and generally accepted professional practice in the field of personnel selection psychology in the choice, development, evaluation, and use of personnel selection procedures designed to measure constructs related to work behavior with a focus on the accuracy of the inferences that underlie employment decisions." The main idea from these Principles is that selection predictor measures should be related to performance on the job.

Conclusion

Personnel selection can be very important for screening applicants out of and *into* jobs. Getting people into jobs where they are qualified and can be successful is obviously desirable for both the hiring organization and the employee. Personnel selection thrives in today's organization under the umbrella of talent management. This concept recognizes that selection is a critical part of building organizational human capital capabilities, in concert with training and performance management initiatives. In sum, personnel selection has a highly important role in human resource management, and, more broadly, in enhancing organizational effectiveness.

Abstract

The article outlines a series of persuasion theories in social psychology. Persuasion may affect both attitudes and behaviors. The following basic approaches are considered: the learning approach, which emphasizes the process of learning attitudes; the consistency approach, which focuses on the importance of consistency between attitudes and behaviors; the attitude–behavior approach, which is concerned with the conditions under which attitudes predict behavior; and the cognitive approach, which is concerned primarily with the cognitive processes that inhibit or promote persuasion.

Persuasion is a fundamental human process that affects almost all aspects of social interaction. In interpersonal relations, mass communication, politics, economics, and even international relations, people attempt to influence the thoughts and behaviors of others. Persuasion usually is concerned with changing the attitudes and consequently (under specific conditions) the behavior of people in a context of relative freedom (for detailed reviews see Crano and Prislin, 2008; Dillard and Shen, 2012; O'Keefe, 2002; Perloff, 2013). In this article, we present various theoretical depictions of the processes implicated in persuasion. Studies of the persuasion process concern the ways people learn to appreciate social environment, maintain equilibrium among attitudes and behaviors, predict behaviors from attitudes, and how they think, more or less attentively, about messages designed to influence. The article presents a number of theories of persuasion that overtime have helped us understand the processes and factors affecting persuasion.

The Learning Approach

The learning approach advanced the idea that to be influenced, the persuasion target needed first to understand and learn the ideas conveyed by the message. Influence in this context was concerned mainly with the way attitudes were developed and formed (*see* Attitudes and Attitude Change). According to this approach, attitudes are nonobservable responses that are learned and thus amenable to reinforcement processes (Allport, 1935; Doob, 1947). These processes may involve Pavlovian classical conditioning, that is, the repeated coappearance in time and space of a neutral stimulus with another stimulus that elicits a strong response, which in turn leads to a perceived connection between the two stimuli (i.e., learning), so that the initially neutral stimulus alone comes to induce the response even in the absence of the original (unconditioned) stimulus. For example, in an exemplar demonstration of this approach, Staats and Staats (1958) repeatedly exposed participants to pairs of words consisting of (1) adjectives with an explicit evaluative tone (e.g., beautiful, kind, pleasant), that is, the *unconditioned stimuli* that produce an *unconditioned response* of liking or disliking, and (2) names of nationalities toward to whom participants presumably did not hold well-formed attitudes (e.g., Swedish, Dutch), the *conditioned stimuli*. The attitudes of participants formed after the conditioning process toward the nationalities significantly mirrored the valence of the adjectives with which the nationalities had been presented, thus eliciting the conditioned response. Similarly, Zanna et al. (1970) found that participants formed a less favorable attitude toward a previously neutrally rated word (conditioned stimuli) when this word preceded the onset of an electric shock (unconditioned stimulus). Although such research on attitude formation has attracted criticism because of its susceptibility to alternative explanations based on demand effects (i.e., participants may infer that researchers expect them to report congruent evaluations to those that were presented in the adjective nationality pairing: see Page, 1969; Fishbein and Middlestadt, 1995), it cannot easily be ruled out in studies that employed more subtle research designs. For example, Berkowitz and Knurek (1969) followed Staats and Staats' design but instead of nationalities, paired two persons' names ('Ed' and 'George') with the same evaluative adjectives. In an ostensibly unrelated experiment, participants met two confederates with the same names and rated their behavior in a way that reflected their previous conditioning (but see Brewer, 1974, for an alternative explanation).

Another proposed underlying learning process responsible for persuasion is operant conditioning. In this case, a behavior is learned because it is *reinforced*, that is, it is followed by a positive outcome or is avoided because it is *punished* (i.e., the behavior has a negative outcome). For example, Hildum and Brown (1956) reinforced their participants' positive or negative attitudes on an issue by providing positive verbal or nonverbal feedback by saying 'good' or nodding 'mm-hmm' after they reported their attitudes. Significant differences were found: negatively reinforced attitudes became less favorable than positively reinforced attitudes. Explanation based on possible demand characteristics of the design were overruled when it was shown that participants, reinforced for expressing either positive or negative attitudes, believed the experimenter was favorably disposed to the issue in question.

The most prolific programmatic research in persuasion based on learning processes is found in reports of the Yale School of Communication and Persuasion, founded by Carl Hovland, which grew from U.S. applied attitude research conducted during World War II (see Johnson and Nichols,

1998). Their research followed a conceptualization of persuasive communication based on Lasswell's (1948) scheme of "who says what, in which channel, to whom, with what effect" (p. 37). In a wide-ranging series of studies, each of these variables was manipulated while holding the rest constant, to assess the effect of each variable on persuasion. For example, the persuasive effects of the characteristics of the source ('who says') were examined (e.g., its credibility: trustworthiness or expertise), as was message characteristics ('what') such as length, structure, order of argument presentation, recipients' characteristics ('to whom') such as self-esteem or intelligence, the channel of communication ('in which channel') such as written or orally conveyed messages, and persuasive outcomes ('with what effect') such as behavior or attitude changes. It was hypothesized that the characteristics of the communication variables would affect the degree to which a recipient would attend a message, comprehend its content, reiterate its arguments, and comply with its position (Hovland et al., 1953). Although the Yale group followed a theoretically eclectic approach (McGuire, 1996), the most prominent underlying process was that of reinforcement. In this theory, attitude change depended on the association of positive or negative attributes of the communication variables with the attitude object. A logical implication of this theory is a correlation between attitude change and the retention of message arguments; however, empirical demonstration of this association was not without problems, and memory of the persuasive message proved a poor predictor of persuasion (Eagly and Chaiken, 1993). Even so, research from the Yale group significantly affected subsequent research on persuasion, although the group's results often are seen as conflicting and not easily integrated (Petty and Cacioppo, 1981).

The Consistency Approach

While the learning approach to persuasion developed within the zeitgeist of behaviorism (and the idea of the determination of behavior by external stimuli), the consistency approach drew from Gestalt theorizing and its ideas of completeness, equilibrium, and coherence. The consistency approach essentially consists of a number of theoretical accounts all based on the common underlying assumption that people prefer coherent and harmonious associations among their beliefs, attitudes, behaviors, and interpersonal relationships (Abelson et al., 1968). A prominent theory among these accounts, cognitive dissonance (e.g., Festinger, 1957; for reviews see Cooper, 2007; Harmon-Jones, 2002), focuses on the associations among a person's cognitive elements (e.g., attitudes, beliefs) and the degree to which these cognitions are consonant with each other and with attitudinally implicated behaviors. For example, a smoker who believes (a cognition) that smoking (a behavior) is unhealthy is thought to be in a state of cognitive dissonance. The individual's attitude is not consistent with the behavior of smoking. Conversely, when people recycle (a behavior) their garbage on a regular basis and believe (a cognition) that protecting the environment is beneficial for the survival of the planet, they hold consonant (i.e., consistent) cognitions. People holding dissonant cognitions, or cognitions that are inconsistent with their behaviors, experience psychological discomfort, or dissonance. The degree of discomfort depends on the importance of the dissonant cognitions (e.g., 'I really like smoking' and 'I am certain that there is a strong relationship between smoking and health problems') or on the number of the dissonant cognitions (when there are more dissonant than consonant cognitions, greater dissonance is experienced). The greater the dissonance people experience, the stronger their attempts to reduce it, as dissonance was viewed as an unpleasant state with drive-like qualities.

The experience of discomfort will motivate people to reduce dissonance (cognitive inconsistencies) and to avoid information that is likely to increase it. People will attempt to avoid dissonance either by adding consonant cognitions (e.g., 'smoking helps me focus on my work') or by minimizing dissonant cognitions (e.g., 'a 90-year-old relative of mine still smokes with no health problems'). When there is a chance for people to be exposed to dissonant information and therefore to experience the discomfort of dissonance, they become selective about what they hear or see: the selective exposure hypothesis proposes that people will selectively expose themselves to information that does not contradict their prior attitudes (Frey, 1986; for a review see Smith et al., 2008).

Festinger and Carlsmith's (1959) *forced compliance study* expanded beyond cognitive conflicts to show how inconsistencies between attitudes and behavior could lead to attitude change. In this study, participants were paid ($1 or $10) to tell others that an experiment they had just completed was interesting and enjoyable (it was not). Surprisingly and clearly inconsistent with reinforcement-based expectations, participants paid only $1 reported more positive attitudes toward the experiment than those paid $10. Festinger and Carlsmith explained these nonobvious findings by postulating that greater dissonance was generated in the low-incentive condition, presumably because those participants could not resolve the inconsistency between their lying about the task and their attitudes toward the task. The study provided a strong case on how behavior can influence attitudes (for a recent replication see by Stice et al., 2008) and also strong evidence contrary to the behaviorist hypothesis, according to which the greater incentive was expected to be associated with more positive attitudes toward the task (see Section The Learning Approach).

Inconsistencies between behaviors and attitudes also can be made salient to people (a manipulation called a 'hypocrisy induction'), and consistent with the dissonance model, which motivate them to align their attitudes and behaviors (e.g., Aitken et al., 1994). In a similar vein, people can be made to predict whether they are going to behave in a normatively acceptable way and subsequently behave in that way (called the 'self-prophecy effect,' see Spangenberg et al., 2003), thereby aligning their attitudes with actions.

The Self-Perception Approach

An alternative account of attitude change following attitude–behavior incongruence was proposed in Bem's (1972) *self-perception theory*. According to this account, attitude change does not happen because of the psychological discomfort related with the inconsistency but by the process of self-observation.

People observe their own behavior and infer their attitudes as they do when they observe other people. This is especially true when there are no other cues in the external environment to account for the behavior. Self-perception theory is a purely cognitive approach, and thus could not predict findings based on the arousal that theoretically was generated in response to dissonance. In a series of important and critical studies, Cooper et al. (1978) and Zanna and Cooper (1974) established the arousing properties of dissonance, and thus rendered implausible the basic assumption of Bem's model. Self-perception theory does account for behaviors resulting from attitude–behavior discrepancies, but only when the attitudes are weak or the behaviors either inconsequential or only slightly discrepant from the attitudes (see Taylor, 1975; Visser and Cooper, 2003).

Attitudes and Behavior

Ultimately, persuasion is about influencing another's behaviors, and this focus is seen in many studies, including those concerned with the purchase of a product, a vote for a political candidate, engaging in safe sex, or driving without drinking. It is therefore important to assess the factors that lead to attitude–behavior consistency. Attitudes can predict or cause a person's actions, and considerable research has focused on the conditions that facilitate or retard the consistency between attitudes and behaviors.

The *theory of reasoned action* of Fishbein and Ajzen (1975) focuses on voluntary actions (e.g., voting for a candidate, or buying a product) and proposes that the best predictor of voluntary action is the intention to perform that behavior. Intention is predicted by the attitudes toward the specific behavior (e.g., 'to vote for the specific candidate is desired because I believe he or she will better people's conditions') and by the subjective norms that concern this behavior, that is, what other people, whose opinions are valued, think about it (e.g., 'my family and friends expect me to vote for this candidate'). The model further details the factors that determine the personal (attitudes) and social (norms) factors. Attitudes are determined by the beliefs that concern the behavior (e.g., 'the candidate publicly supports pro-environmental policies,' which I approve of) and the expectancies associated with these beliefs (e.g., 'the candidate will be able to implement these policies'). Norms are determined by the beliefs that concern what significant others think about the behavior (e.g., 'my family wants me to vote for the candidate') and the degree to which the person is motivated to comply with significant others' desires (e.g., 'I would like to follow what my family wants me to do on this issue').

The *theory of planned behavior* (Ajzen, 1991) extends the theory of reasoned action by including, in the predictive model, the belief concerning the degree to which a person consciously controls the critical behavior; that is, whether people think it easy or difficult for them to perform the specific behavior. For example, people may have positive attitudes (e.g., 'quitting smoking is good') and supportive norms (e.g., 'my family would like me to quit smoking') toward a behavior but the important belief about the control over the behavior (e.g., 'I do not think I am able to quit smoking') may determine the predictive power of attitudes and norms on the intention. A number of reviews and quantitative meta-analyses of empirical studies have supported both theories (see Albarracin et al., 2001; Armitage and Conner, 2001; Hardeman et al., 2002).

The Cognitive Approach to Persuasion

The metatheoretical dominance of cognitive approaches across many subfields of psychology during the last decades has been evident in persuasion research as well. In one of the first attempts to bridge learning and cognitive principles in persuasion, Greenwald (1968) pointed to the importance of thinking and elaborating the persuasive message to attitude change. He suggested that persuasion was mediated by "the content of attitude-relevant cognitions elicited (and thus rehearsed and learned) during the persuasion situation" (p. 167). In this view, then, attitude change depends on the valence of thoughts generated when considering a persuasion message. The more favorable the thoughts developed in response to the message, the greater the attitude change in the direction of the message. An important methodological development that was instrumental to the progress of the cognitive approach was the thought-listing technique (see Petty and Cacioppo, 1986) in which participants list the thoughts they had as they were exposed to a message, which are later analyzed for message favorability. This focus on the cognitive responses to the message sparked a new approach to persuasion that dominates today's understanding of persuasion processes.

The persuasion approach proposed that the recipient of a persuasive communication would not necessarily work to draw a logical conclusion regarding the issue presented in the message. Depending on a number of variables of the communication context, recipients will sometimes follow cognitively effortful ways of processing the message, but at other times will follow cognitive shortcuts, which require considerably less cognitive effort to reach an evaluation of the attitude object. Two models that dominated the cognitive approach are the elaboration likelihood model (ELM; Petty and Cacioppo, 1981, 1986; Petty and Wegener, 1998), and the heuristic-systematic model (HSM; Chaiken, 1980; Chaiken et al., 1989; Chen and Chaiken, 1999). Both of these dual-process models propose two qualitatively different cognitive routes to attitude change, one characterized by effortful elaboration of a persuasive message, and the other characterized by near-effortless elaboration.

Elaboration Likelihood Model

In the ELM, the effortful cognitive pathway is called the *central route*. It involves a thoughtful processing of the message, where recipients attend its content and try to evaluate it in terms of their prior knowledge and attitudes. The less effortful path is called the *peripheral route*. It involves a consideration of various aspects of the influence setting (such as the characteristics of the source), with considerably less analysis of the content of the message. Message elaboration within this framework is

perceived as a continuum, a variable from high to low depending on the route recipients follow, which depends on two variables, the receiver's *ability* and *motivation* to process the message. When both ability and motivation are high, that is, when people are able to understand and elaborate, and at the same time are motivated to do so, they are likely to follow the central route of processing and devote significant cognitive resources in responding to the message. Ability is influenced by such factors as people's prior knowledge (the more recipients know about the content of a message, the more they are able to elaborate it) or possible distractions in the influence context, such as noise (the greater the distraction, the less able are recipients to engage in issue-relevant thinking) or cognitive business (*see* Attitudes and Attitude Change).

Motivation also is affected by a number of variables such as personal involvement with the issue at hand, defined as the degree to which recipients perceive relevance between the topic of the message and themselves personally. The model posits that personal involvement is an important variable for issue-relevant thinking. The greater the involvement, the greater the message elaboration. Another factor that affects message processing is recipients' *need for cognition*, which is defined as the degree to which individuals engage in and enjoy thinking. People who enjoy thinking hard are more motivated, and more likely to engage in central processing.

A central assumption of the model is that the effect of message elaboration on attitude change depends on the valence of thinking produced. When favorable thoughts toward the argument exceed unfavorable thoughts, then attitude change toward the advocated position is expected. Valence of thoughts may depend on recipients' prior attitudes, with those already holding positive attitudes toward the attitude object inclined to produce more favorable thoughts as compared to those holding less positive prior attitudes. The qualities of the persuasive arguments, however, are of crucial importance in predicting the outcome of a persuasive attempt. The ELM makes a distinction between strong arguments (characterized by good evidence, use of logic, and powerful reasoning) and weak arguments (e.g., poorly reasoned, weak or ambivalent evidence), with the former leading to more favorable thoughts, assuming that recipients follow the central route. In the empirical examination of the model, and to assess whether a variable of the communication context (e.g., characteristics of the source or the message) instigate central or peripheral processing, the variable is crossed with argumentation quality and is examined at which level of the credibility variable a difference between strong and weak arguments is noticed. Differences in responses to strong and weak arguments, with the former leading to more favorable thinking and greater attitude change, are taken as indicative of central processing. The distinction between strong and weak arguments is central in the model, but it has attracted criticism because of its lack of solid theoretical basis and its reliance solely on empirical pretesting of the arguments (see Eagly and Chaiken, 1993; Stiff, 1986).

When elaboration is low and recipients of an influential communication do not have the ability or the motivation to process a message centrally, the model suggests that peripheral processing will become dominant. Although not a singular type of processing, but rather a host of different kinds of processing modes, peripheral processing is characterized mainly by lack of elaboration of the content of the message. One kind of peripheral processing (others include classical and instrumental conditioning, attributional thinking, etc.) is the use of cognitive heuristics, established rules of thumb used to provide a shortcut to decision-making ("Do I agree with this message or not?"). Such heuristics often concern the source of the influential message: for example, when the source is perceived as expert and trustworthy, recipients who are unlikely to elaborate a message are likely to agree and comply without paying much attention to message's arguments. A similar pattern of results is evident when the source is likable; again at the lower end of elaboration continuum, more likable sources are more persuasive than less likable ones. The consensus heuristic concerns whether other people support the message's position as well. Again at the low end of elaboration continuum, people will agree with a position supported by the majority as compared to one supported by a minority.

The two routes to persuasion are not only different in terms of the quality of thinking connected with them, but also the consequences they have on changed attitudes compared to the attitudes that result after peripheral processing. Attitudes that result after central processing are stronger, more enduring in time, more resistant to counter-persuasion, and more predictive of behavior.

An important characteristic of the ELM is that many variables within the communication context can affect message elaboration and resultant persuasion, and in many different ways (see O'Keefe, 2002). They can influence elaboration, serve as arguments, or as peripheral cues. For example, source credibility may be considered a peripheral cue, but it also can serve as an argument that increases persuasion (Petty et al., 1999).

Another assumption of the ELM is that variables not only can affect the degree of elaboration, and thus the underlying route to persuasion, but also introduce a central route processing bias. This bias may motivate the recipient to process the advocated position so that it can be either verified or falsified. This confirming or disconfirming mode of processing can be affected by variables such as prior knowledge or forewarning. In the former case, recipients elaborate knowledge-consistent information more deeply and produce favorable cognitions; in the latter case, recipients are motivated to counter-argue the message and produce unfavorable thoughts.

The ELM has provided a comprehensive theoretical framework of persuasion phenomena and instigated a prolific program of research. It has attracted criticism, however, on the difficulties of the assessment of elaboration independent of its effects and of the prediction of the specific role a variable can play. Moreover, predicting when central and peripheral processing can co-occur is not without problems, as the conditions under which this can happen are not clearly specified (see Bohner and Schwarz, 2001).

Heuristic and Systematic Processing

The *heuristic-systematic processing model*, similar to the ELM, proposes two different processing modes, one effortful, characterized by issue-relevant thinking called *systematic* and one effortless, called *heuristic* (Bohner et al., 1995; Chaiken et al., 1989; Chen and Chaiken, 1999). Like ELM, HSM describes

message elaboration as a continuum affected by recipients' abilities and motivations. However, HSM is differentiated from the ELM in how it details the effortless mode of processing, the interaction between the processing modes, and the motivational underpinnings of processing modes.

Systematic processing involves recipients' active evaluation of message content and judgment formation or attitude change utilizing prior knowledge (Chaiken et al., 1989). Heuristic processing, a less effortful mode of processing that does not involve strong attention to the content of the message, is defined narrowly as involving the application of heuristics, that is, established cognitive schemata that govern evaluation and decision-making in a communication context (e.g., 'An expert source is right most of the time and thus should be trusted'). This definition is more specific than ELM's peripheral processing, which encompasses a number of different processes (e.g., classical conditioning and so on).

The ways that systematic and heuristic modes interact in the persuasion process are also methodically specified in the HSM (Bohner and Schwarz, 2001). When message receivers are unable or unmotivated to process a message, heuristic processing will predominate, as this processing mode requires minimal effort and cognitive resources. However, at the higher end of the elaboration continuum, systematic and heuristic processing may operate simultaneously, either independently or interactively. Bohner et al. (1995) have developed an empirically supported explication of these singular or interactive processes, which they termed the *co-occurrence hypotheses*. The first two hypotheses concern the case in which both processing modes have independent effects on attitudes: In the *additivity hypothesis* case, heuristic and systematic processing may independently affect attitudes. This is evident only when the two processes do not contradict each other (e.g., when an expert provides very weak arguments). However, according to the *attenuation hypothesis*, because systematic processing "often provides the individual with more, and subjectively more relevant, information any additional effects of heuristic processing may be suppressed" (p. 423).

Bohner et al.'s next hypotheses concern cases in which the two modes of processing interact: The *bias hypothesis* holds that if a message contains both strong and weak arguments, or is of ambiguous valence, it is possible that initial heuristic processing will bias systematic processing so it is assimilated to the valence of the heuristic cue. For example, Chaiken and Maheswaran (1994) manipulated message strength and source credibility and showed that participants highly motivated (and able) to elaborate the message, who received a message of both strong and weak arguments assimilated their attitudes toward the heuristic cue of source credibility. However, when they received messages containing only strong or weak arguments, the former led to greater persuasion than the latter irrespective of source credibility. Hence, the effect of systematic processing suppressed the effects of heuristics, as the attenuation hypothesis would assume. Finally, according to the *contrast hypothesis*, violation of expectancies based on heuristic processing can lead to contrasting systematic processing. More negative thinking is expected when positive expectancies are violated, and when negative expectancies are violated, more positive thinking is expected. This bias was observed in a study by Bohner et al. (2002), where participants rated a message with weak arguments provided by experts less favorably than the same message provided by nonexperts.

The extent of processing motivation can largely be accounted for by the HSM's *sufficiency principle*, which suggests that people attempt to attain sufficient confidence in their judgments and attitudes. Sufficiency is determined by two concepts, the sufficiency threshold (ST: the desired confidence) and actual confidence (AC). When AC is lower than desired, individuals are motivated to systematically process the message. The greater the difference between ST and AC, the greater systematic processing is expected. The less difference between ST and AC, the more is heuristic processing expected. Desired confidence may increase depending on personal relevance and involvement and AC may decrease depending on the difference in the valence of heuristic cues and content (Maheswaran and Chaiken, 1991).

Finally, the HSM describes multiple motives that underlie the extent of processing; these involve *accuracy*, *ego defense*, and *impression motivation*. Individuals may try to attain attitudes that are valid reflections of reality (accuracy-motivated processing is assumed to be more open-minded); they also may try to defend self-defining beliefs and values, and thus may adopt attitudes to look good and be accepted by others (both defense- and impression-motivated processing are assumed as more biased). Differences between desired and AC determine the strategy that will be followed (Bohner et al., 2008).

The Unimodel

A challenge to the dual-process conceptualization of persuasion that has dominated the field during the last decades was advanced by Kruglanski and Thompson (1999). They proposed the *unimodel*, a single process alternative to persuasion accounts. According to this theory, effortful (central or systematic) and effortless (peripheral or heuristic) processing modes incorporate functionally equivalent types of evidence. Evidence is defined as any type of information that can be perceived as pertinent to the judgments an individual will make. The unimodel does not accept the distinction between cues and arguments that has been instrumental to the dual-process models; rather, it suggests that all information relative to the source (e.g., credibility), the message (e.g., quality of argumentation), or the context (e.g., channel modality) can be considered evidence that an individual can take into account to reach a conclusion about an issue. The model has been characterized on the basis of its emphasis on the relevance of evidence to the conclusions drawn by the recipient, as a functional theory of persuasion (see Johnson et al., 2005) that relates the goals of receiver with the persuasive information. It has motivated interesting and confirmatory research, but has not attracted as much attention as the dual-process approaches.

Concluding Remarks

Persuasion theories have provided a wealth of information detailing when and how people are persuaded. The theoretical approaches presented here have focused on different aspects of

persuasion process that have contributed to a greater or lesser degree to our understanding of persuasion. The contemporary dual-process models of persuasion address the importance of ability and motivation to elaboration, and the valence of recipients' thinking about persuasive messages. They have integrated and accounted for a significant number of previous persuasion phenomena and guided contemporary research in the field. However, the challenges these models face are both theoretical (e.g., the explanatory power of the unimodel remains to be seen) and applied regarding significant social domains (e.g., improvement of health behaviors or reduction of prejudice).

Abstract

Sex, sexuality, and human intimacy are universal and strongly influenced by individual and societal factors. Cultures determine abnormality and normality across the range of human behaviors. Historical, religious, legislative, and technological shifts have also influenced the classification, acceptance, attitudes, and distribution of sexual practices.

Paraphilic disorders pose unique challenges to social scientists, clinicians, and the criminal justice system. The private nature of the majority of practices and their legality make study particularly challenging and fraught with limitations. The dearth of knowledge of these disorders is an invitation to researchers of all fields relating to sexual practice.

Introduction

Sex, sexuality, and human intimacy are universal phenomena that are strongly influenced by personal orientations and fantasies. Attitudes toward sex, sexuality, orientation, and procreation are also strongly influenced by societies, their history, and cultures. These identities influence our latent and manifest world views, and invariably how we think and how our attitudes develop. Societies and cultures determine deviancy and normality across the range of human behaviors. This relationship involves a complex interplay of factors, defining norms of acceptable behavior and permissible variants.

Previously known as sexual deviance, perversions, or aberrations the range of abnormal sexual behaviors is now referred to as paraphilias.

The word 'paraphilia' that is derived from Greek means beyond or irregular (*para*), a love of (*philia*), and has less pejorative implications than previously used names.

Brief History

Sexual Orientation and Practices Are Steeped in History

Antiquity

The ancient Greeks often ascribed different forms of sexual behavior to their gods. Zeus was portrayed as having relationships with animal or inanimate objects forms, such as a cloud or a shower of gold, and his objects of desire were of both sexes. On the other hand, Hercules cross-dressed, while Theseus and Achilles also wore women's clothes at times (Licht, 1969; Bullough, 1976). Hippocratic Greeks gave advice on sexual practice and the vitality of life; for example, "sexual intercourse should be more frequent … in winter … and for older men more than the younger."

In the medieval West, the perceived wisdom was that men and women shared the same physiology, the male being perfect version and the female flawed. Female genital organs were believed to be inverted and inferior versions of male genitalia. Menstruation was felt to be the leaking of vital body fluids which men discharged as semen.

History observations and record found paraphilias were present in diverse cultures and across time periods. Sometimes linked with religious practice, rites of passage and cults, a variety of sexual practices flourished. Archaeologists have also found cave paintings and figurines depicting sexual activity from several 1000 years ago.

The more recent development of sexology led to the development of diagnostic and classificatory systems as asylums, jails, and hospitals were faced with managing a range of erotic dispositions and behaviors found unacceptable if not abhorrent to the different societies.

Classifications

Different labels have been applied to sexual behaviors over the centuries. However, it was not till the eighteenth century that attempts to classify and label started in the West. Categories varied with each culture considering, approving or disapproving, behaviors based on the prevailing sexual climate. Classifications offer an insight into the thinking of historical periods.

The Marquis de Sade (1740–1814), while imprisoned in the Bastille, wrote detailed descriptions and short stories of sexual behaviors, proposing a classification a century before his successors, Krafft-Ebing, Havelock Ellis, and Freud – his discourses about sex and morals, *120 Days of Sodom*, being the most memorable work on perversion of the time. De Sade requested people not to mock those with deviant impulses, but to look upon them as one might a cripple, with pity and understanding. De Sade proposed the following classification for sexuality (Gorer, 1963):

(a) People with weak or repressed sexual desires
(b) Natural perverts (born so)
(c) Libertines – people who imitate group (b), but wilfully rather than naturally.

Sade also described sexual acts involving different body fluids, sperm, blood, urine, saliva, and feces.

In the nineteenth century, Darwin in his theory of evolution influenced the thinking of Ernst Haeckel, who suggested that sexual perversions reflected a return to an earlier developmental stage that had become fixated, so that perverts, like other races and women, were at a lower evolutionary point.

Succeeding generations of physicians, sociologists, and therapists continued debating over alternative classifications of perversions. Krafft-Ebing for instance proposed life was

a struggle between instinct and civilization, and mental disorders created no new instincts, but altered existing ones. Like many others he felt excessive masturbation triggered sexual perversion. Krafft-Ebing's *Psychopathia Sexualis* highlighted his classification as below:

Group 1: Deviation of the sex impulse. Too little sexual feeling (impotence, frigidity); too much (satyriasis and nymphomania), and sexual feeling appearing at the wrong time (in childhood or old age) or being directed wrongly (at children, the elderly, or animals).

Group 2: Sexual release through other forms of activity (inflicting or receiving pain or sexual bondage).

Group 3: Inverted sexuality (homosexuality, bisexuality, and transvestism).

Krafft-Ebing's works had many revisions over the 12 editions. Krafft-Ebing encouraged better understanding of 'perverts' referring to them as 'stepchildren of nature.' His belief that most perversions were mainly congenital was challenged by Alfred Binet who argued that fetishism involved, the fetish taking different forms, for example, an obsession with the color of the eyes, bodily odors, clothing, or different inanimate objects. He opined heredity could not determine this choice, and it was more likely a childhood phenomenon. However, only few developed perversions after childhood events. Binet concluded there may well be an innate morbid condition in some individuals.

Freud on the other hand theorized that developmental stages from infancy to adulthood replicated the moral development of humans, from sexual promiscuity, to perversion, and finally heterosexual monogamy. The healthy infant negotiating the Oedipal complex and castration anxiety (a narrative of incestual love) was felt to develop neurosis if unsuccessful with transitions. Freud believed perversions were a consequence of arrested development from trauma culminating in stagnation in sexual pathways. Successful negotiation of childhood difficulties occurred in some due to constitutional factors and moral evolution. Freud classified as deviants individuals with sexual interest other than normal vaginal intercourse. His works are rich in phallic objects and sexual reference.

Current Classification

The modern era has seen a shift in classification of sexual practice. Following centuries of being associated with illness, loss of vital force, and a cause of insanity masturbation is no longer considered a deviant act. Similarly, homosexuality, which had previously been classified a disorder, was removed as a paraphilia in the 1974 edition of the *Diagnostic and Statistical Manual of Mental Disorders*.

The Diagnostic and Statistical Manual of the American Psychiatric Association (DSM-5) defines a paraphilia as "Any intense and persistent sexual interest other than sexual interest in genital stimulation or preparatory fondling with phenotypically normal, physically mature, consenting human partners." Hence, any sexual interest outside normophilic sexual interests. This article explores the range of normophilia and disorders outside its boundaries.

Paraphilic Disorder

A paraphilia that is currently causing distress or impairment to the individual or a paraphilia whose satisfaction has entailed personal harm or risk of harm to others is described as paraphilic disorder.

Preferential sexual interests affect sexual activity and can manifest in erotic activities as well as erotic targets. Paraphilias often come to the attention of mental health professionals and social care in the context of legal complications. Where consenting adults in private situations perform these acts they are unlikely to have clinical contact. In light of this, significant distress or unlawful nature of some activities may trigger referral to legal or medical interventions.

Given the large range and diversity of paraphilic disorders a comprehensive list is beyond the scope of this volume. Table 1 illustrates a number of commoner disorders.

The DSM-5 highlights "knowledge of and appropriate consideration for normative aspects of sexual behaviour are important factors to explore to establish a clinical diagnosis and to distinguish a clinical diagnosis from socially acceptable behaviour."

The role of sexual activity is unavoidably fundamental to the preservation of humanity. However, non-procreational sexual activity is influenced by factors such as the availability of sexual partners, opportunity, individual preferences, and fantasies. These individual factors are set against a backdrop of culture, norms, taboos, religion, mores, and values of the society.

Behaviors that may externally appear similar may have different explanations. For instance, a man may dress in female clothes for a fancy dress party, for sexual pleasure and gratification or part of a therapeutic gender reassignment process. Superficially, each situation involves cross-dressing in a man however the contexts are markedly different. Bhugra and de Silva described the transitional role of uniforms as symbols traversing fashion, fantasy, and fetish.

In some situations (e.g., prisons), absence of heterosexual opportunities may limit heterosexual individuals to engaging in homosexual activity. This sexual behavior may not necessarily reflect individual sexual preference or fantasies.

Furthermore, society may influence perception of the number of partners and acceptable frequency of sexual activity (sexual addiction). In essence, sexual activity should always be considered in context.

While paraphilias are universal phenomena the prevalence, distribution, and legal status may vary in individual societies.

This article explores the nature of paraphilias and the controversies associated with less common sexual behaviors.

Nature and Nurture of Sexuality

Gender roles vary in different societies. While men and women have equal rights and opportunities in some, men dominate in others and rarely do women control the administration of a community. Hofstede described the dimensions of 'masculinity–femininity' in human groups. In high masculinity societies women have restricted opportunities in vocation or societal hierarchy. There are higher degrees of individualism, financial reward, and limited support for the

Table 1 Specific paraphilic disorders

Paraphilic disorder	*Description*	*Prevalence (from DSM-5)*
Voyeuristic disorder	Urge or practice of observing an unsuspecting person who is naked, undressing, or engaging in sexual activity, or in activity deemed to be private.	Most common of potentially law-breaking paraphilias. Population prevalence unknown. Highest lifetime prevalence 12% males; 4% females.
Exhibitionistic disorder	Exposing one's genitals to an unsuspecting person or performing sexual acts that can be observed by others.	Prevalence unknown. Highest population prevalence 2–4% male. Lower in females.
Frotteuristic disorder	Touching or rubbing against a non-consenting person.	Frotteuristic acts in up to 30% adult males in general population.
Sexual masochism disorder	A desire to be humiliated, beaten, bound, or made to suffer for sexual pleasure.	Prevalence unknown. 2.2% male; 1.3% female reported in past 12 months (Australia).
Sexual sadism disorder	Sexual pleasure through the infliction of pain or humiliation on another person.	Prevalence unknown. 2–30% reported.
Paedophilic disorder	Sexual preference for prepubescent children.	Population prevalence unknown. Highest possible male prevalence approximately 3–5%; female lower unknown %.
Fetishistic disorder	Use of inanimate objects to gain sexual excitement.	Unknown.
Transvestic disorder	Arousal from clothing associated with members of the opposite sex.	Unknown but rare.
Other specified paraphilic disorder	Other paraphilias include the use for sexual purposes of corpses (necrophilia), animals (zoophilia), feces (coprophilia), enemas (klismaphilia), and urine (urophilia).	Unknown.

weaker in these groups. Conversely, feminine societies are relationship oriented and focus less on emotional or social differentiation. Individualistic societies with less restricted or hierarchal structures may have a greater expression of paraphilias. Such expression may not indicate the true prevalence however.

Sexual practices may follow set cultural scripts that both promote and discourage different types of sexual behavior (Reiss).

Sociocultural scripts of sexual behavior may be inborn biological (nature) or may be acquired (nurture and environmental). Cultural transmission of sexual roles and behaviors may be age, gender, or position specific through folklore, song, dance, or depiction in artwork. Societies may limit or promote behavior through rites of passage into manhood – for example, affirmation of a female partner's virginity with blood-stained sheets after the consummation of marriage.

Segall et al. (1999) argue that the role of nature (biology) indicating sexual attraction and arousal are biological processes, involving cognitions, nerve transmissions, and physiological changes before sexual activity. These important biological mechanisms play a key role in the process and manifestation of normal and paraphilic behaviors in all societies. Evidence supports the role of biological, cultural, and individual factors in the development of paraphilias. The weight given to each component remains uncertain and will be explored further in this article.

Sexual Behaviors and Attitudes

Standards of what constitute the normal range of sexual attraction, arousal experiences, and behaviors are difficult to define. For instance, this may range from body morphology, skin tone, eye color, hair, to fragrance.

Bullough proposed a classification of societies and cultures as either 'sex positive' or 'sex negative.' Sex-negative cultures see semen loss and even intercourse as a flaw and sexual temperance is encouraged. Sex-positive cultures on the other hand permit the pleasurable, gratifying and non-procreative aspects of sex.

History

Sexual attitudes and values have changed over centuries. Early Greeks and Romans recognized and tolerated alternative sexual behaviors with shifting attitudes toward sexuality. Religious doctrines and belief systems were also promoted by different scriptures and teachings. Over millennia, procreation has been essential to sustaining society and activities such as labor (farming) and military workforce. Non-procreative loss of semen was associated with loss of potent vital energy and the reproductive capability of the individual as well as the society.

Religion

Early Christianity generally disapproved of non-procreative sex. In addition, it disapproved of sex outside marriage and this consequently became a pillar of the Ten Commandments. Over time, competing and parallel religious systems led to different interpretations of the Abrahamic doctrines. However, marriage did not automatically confer the right to sexual intimacy and was seen more as a relationship duty rather than a source of pleasure.

Islamin contrast appeared slightly more accommodating, with the historical appreciation of the sexual traditions of pre-Islamic Arabs. Women were sought for wedlock and not debauchery; however, a contradiction to this was that women were seen as lesser and subservient to men.

Hinduism, as a religion and philosophy, was seen as sex positive as vividly illustrated in the carvings of sex acts in temples and Kama Sutra. The Kama Sutra as numerous erotic

Hindu classics covers numerous features of courtship and sex acts. While superficially sexually liberal, there are sexual restrictions in the faith. For instance, adultery and intercaste relationships were discouraged. However, transsexualism and transvestitism which would otherwise be termed deviance, were tolerated. As societies have evolved, changed, and imbibed new customs, the values and attitudes regarding sexual activity and sexuality have changed. Religion has been a potent vehicle of these attitudes and practice.

Sexual values and attitudes have changed as societies evolve and imbibe new customs. Religion has been a powerful transmitter of attitudes and practice across regions of the world: for example, Pentecostal churches in Africa. Historical record and artistic portrayal of brothels, sex acts, homosexual prostitutes, pornographic media, and the trade in sex toys between nineteenth and twenty-first century England highlight shifting societal trends. On the whole, acceptance of female sexuality is limited and in some parts of the world, deviation from proscribed roles may culminate in death for example Taliban Afghanistan where even female education is deemed immoral.

Prevalence of Paraphilias (see Table 1)

There is a dearth of empirical data on the prevalence and distribution of paraphilias. Investigation into the prevalence of paraphilias and other sexual behaviors face numerous challenges such as embarrassment to acknowledge behaviors and the illegal status of some sexual behaviors even in the most liberal societies. Furthermore, it is difficult to ethically and objectively verify study results. Paraphilias in clinical settings are more likely to be in the context of legal issues than voluntary referral. Research is limited in less permissive (mainly non-Western) societies.

Given the challenges associated with researching paraphilias, proxy measures have been used in some case. Exploring the relative prevalence of some paraphilias, Dietz and Evans monitored the use of pornographic magazines. It was hypothesized that choice of pornography was likely to reflect underlying fantasies. The most common imagery found was bondage and domination. Magazines often presented women wearing lingerie and high heels. A limitation of studies like this is the variation in distribution of pornography and inability to generalize or extrapolate findings to actual behaviors. The growth and variety of pornographic material on the Internet would limit such research currently.

In Sweden, Langstrom and colleagues, in a survey of sexuality and health among 2450 randomly selected 18–60 year olds asked questions regarding paraphilias and problem sexual behaviors: 3.1% of respondents reported sexual arousal by exposing their genitals to a stranger on at least one occasion and 7.7% at least one incident of arousal spying on others having intercourse. There were associations with being male, psychological difficulties, drug and alcohol use, and lower life satisfaction. Voyeurism was nearly three times commoner in men and they were twice as likely to expose than women. A relationship between early childhood experience such as separation from parents and some paraphilias was also observed.

Langstrom and Zucker observed 0.4% of women and about 2.8% men acknowledged at least one episode of transvestic fetishism. These individuals were more likely to have had childhood separation from parents, abuse, same-sex sexual experiences, high-frequency masturbation and sexual arousal with the use of pornography. They also reported higher rates of voyeurism and exhibitionism.

Further review of the sample found an association between hypersexuality and paraphilias. Men in this category were more likely to be young with early sexual activity, experienced separation from parents, and reside in major cities. They were more likely to be involved in same-sex behavior, sadomasochism, voyeurism, exhibitionism, and fund sex. Paradoxically, they were less satisfied with their sex lives and more involved in risk-taking behaviors such as substance misuse, gambling, and alcohol use. These findings suggest some behavioral and social associations with paraphilias which may tenuously contribute to or complement paraphilias.

Gender

Developmentally, boys explore genital pleasure more readily and perhaps younger than girls. It appears societies are more tolerant or permissive of male expression of sexuality while restricting females. The developing girl may become aware of genitalia, menses, and sexuality with embarrassment unlike many of their male counterparts.

The current body of evidence shows a male prevalence in the majority of paraphilias. It may reflect men being more actively in sexual intimacy than women. Men have more frequent sexual thoughts with a desire for physical pleasure while women are more inclined to engage in sexual intimacy when there is an emotional bond.

Paedophilic Disorder

In Ancient Greece and Rome, adult–child sex was permitted and acceptable practice. Greco-Roman art depicting nubile children and adults in poses were common features of the social culture. However, there are also historical accounts of child safety concerns in some societies (e.g., Green).

The developmental stage or age of consent for sex is mainly influenced by the rules of the land, culture, and religious factors as is the case with marriage. There may be variation that may vary for heterosexual and homosexual activity.

In Western societies, paedophilia is socially and legally undesirable with significant criminal justice and clinical resource invested in its management. The global web of the Internet has made this more difficult with the absence of geographical and legislative boundaries as is the case with the 'dark net.'

A number of social deficits have been reported in some paraphilias. A number of paedophiles have for instance been found to have inadequate social skills, while Langevin found them shy, socially withdrawn, passive, and lacking assertiveness. Many paedophiles experienced disturbed childhoods with for example sexual abuse, inadequate parenting, and family dysfunction.

Most research into paedophilia has been in offender populations. A survey by Wilson and Cox observed 71% of male paedophiles reported an attraction to boys aged 12–14 years

and 12% a preference for girls aged 8–10 years with sexual fantasies in about half. While Seto, Cantor, and Blanchard propose child pornography may be a valid diagnostic indicator of paedophilia, this may actually relate to arousal and fantasy rather than actual behaviors. It is very difficult to extrapolate these findings to the general population.

Fetishistic Disorder

Kaplan has written extensively about fetishes from a psychoanalytic perspective suggesting the behaviors are underpinned by the need to transform something unfamiliar and intangible to something familiar and tangible as a feature of the fetishism strategy. The etymological and non-sexual use of the word is related to inanimate items such as carvings, feathers, or artificial material. Substances such as leather, latex, and rubber have also been linked with fetishism in different societies.

The sexualization of these objects may facilitate dealing with internal ambiguous anxieties.

Kaplan suggests that "fetishism permits certain details into the foreground of experience … thereby masking or disguising other features and casting them into the background shadows and margins" (page 6). The purpose of the fetish is masked and the object of fetish becomes more prominent and dramatic.

The Fetish Foot and Shoes

The historical foot binding of Chinese females has been proposed as a cultural fetish (Kaplan). Beginning in the twenty-first century BC, the practice was initially restricted to upper classes – the ruler's mistresses, concubines and dancing girls in specific regions of the country. Over time, foot binding spread across China. Male control in such a manner can be considered fetishsitic control over the object. The modern-day feet continue to draw attention with sexualization of high heel shoes which draw attention to the legs. The role of feet and shoes in sexual fantasy shows variation, for instance, rural, desert, or snow-capped communities with a more practical emphasis on footwear are unlikely to sexualize high heel shoes.

Procreation or Pleasure

Hypothetically, sociocentric cultures that promote sex for reproduction are less likely to develop sexual fetishes, and if so lower rates than egocentric cultures with a greater emphasis on the pleasure of sex.

Increasing globalization, with rural–urban and international migration, may lead to increasing experimentation and changing expectations from sexual partners round the world.

Cultural Behavior or Paraphilia?

Some culturally acceptable behavior may be perceived as paraphilic in other societies. In Papua and New Guinea for instance, the Sambian boys perform fellatio on older tribesmen as a right of passage, swallowing their semen for growth and strength. After about a decade in homosexual relations, the younger males develop a fear of being polluted by women. Once at the stage for heterosexual marriages they discontinue the earlier homosexual practice. These behaviors are limited to tribal rituals and not for pleasure but initiation rituals to assist with the development of masculinity.

Culture modulated reversal from homosexual to heterosexual practice illustrates how behavior considered or attributed paraphilic can be normalized and subsequently reversed according to societal norms.

Technological and digital innovations with the Internet, phones, and camera devices have altered patterns of voyeuristic behavior and proximity is no longer required to intimately observe others.

Similarly, exhibitionism occasionally takes advantage of these technologies over the Internet or televised events. 'Flashing' whereby an individual exposes genitals or breasts in public events is not commonly described in non-Western societies. Nudist colonies on the other hand promote non-sexual total exposure as a way of life.

There has been a growth in industry of sex aids and 'toys' over the years such as vibrators. These items substitute intimacy in some individuals while used as an erotic adjunct in some relationships.

Others achieve sexual fulfillment with telephone 'sex-lines,' 'cybersex,' or virtual reality sexual scenarios.

Frotteurism, a disorder commoner in crowded locations such as congested trains and busy gatherings is likely to be higher in urban than isolated rural settings. In such settings the frotteur and their intentions are not easily identified. It stands to reason that distribution of this disorder is uneven.

Sexual Masochism

Sexual masochism is the deliberate or voluntary participation in an activity that involves being humiliated, beaten, bound, or otherwise abused to experience sexual excitement. Frequently associated with masochism, sadism involves the infliction of physical or mental suffering (pain, humiliation, or terror) on the sexual partner to stimulate sexual excitement and orgasm. Sadistic fantasies linked with complete control of the other are particularly dangerous and may be fatal. Masochistic behaviors that involve self-asphyxiation as part of a masturbatory ritual can also result in accidental death.

The Biology of Sexual Behaviors

Sexual processes and pathways are complex and involve the interplay of biological and environmental factors. So far, social and environmental factors have been explored. Intrauterine development of the human brain is somewhat modulated by the action of the male sex hormone, testosterone. Its presence is key to male development and female development in its absence.

Berridge and Kringlebach present biological and physiological theories. Stating that brain processes of emotion, motivation, and affect are influenced during development with active mechanisms of the brain responding to reward stimuli. It

is suggested that the rewards consist of liking (a conscious cognitive process) and wanting (the motivation for reward through incentive salience) in addition to learning processes. Through this process, different stimuli and experiences produce different degrees of pleasure or displeasure as is the case for preferences in fragrances or body morphology. Noxious stimuli in sexual activity on the other hand are complexly interwoven with emotions.

Behavioral and cognitive ingredients of pleasure may be individually or socially determined. Personal pleasure (whether normal or disordered) may relate to social pleasure or alternative sensory stimuli. In paraphilic disorders, behavioral and cognitive processes seek to enhance pleasure with individual, social, or combined rewards.

Neuroanatomy, Neurochemistry, and Neurophysiology

Various brain structures have been found to mediate reward. For instance, the experience of pleasure has been associated with the orbito-frontol cortex with the support of other subcortical structures and neurochemical transmission such as dopamine. The hypothalamus is largely concerned with the hormonal control of reproduction. Sexual fantasy however requires the cognitive processes of the cerebral cortex that processes complex information, knowledge, and emotion associated with sex. Furthermore, following head injury or the use of psychoactive substances, paraphilic behaviors may manifest in some individuals. This may be associated with the ensuing loss of inhibitory control or personality change.

Frontal and temporal lobe EEG differences have been observed among sex offenders with paraphilias, however they lack specificity.

The neurosciences offer exciting opportunities through neurobiology, neurochemistry, and neuroimaging of normal and abnormal sexual activity. In addition, advances in genetics and epigenetics may help us understand the nature of human sexuality.

Oxytocin, a neurochemical has been found to have a biological modulating influence on emotions, of pleasure and love sensations. The role of oxytocin in the treatment of satiety and emotional dysregulation is being investigated.

Hypothalamic and mesolimbic dopamine pathways have been suggested by Pfaus et al. with endogenous opioid activation in the brain as a basis of sexual reward.

They hypothesize that a 'love map' of components, feelings, movements, and interactions associated with sexual reward occur during a critical period of early sexual experience.

There is also evidence of the impact of neurodevelopmental difficulties and head injuries on the presentation of paraphilias, for example, learning disability and specific regional head injuries for instance frontal lobe with impaired executive function and personality change. Childhood head injury has been reported by Blanchard et al. (2006). Blanchard et al. (2006) also suggested that some deviant sexual behaviors result from pathological or pathogenic developmental variables, which may impede normal sexual development.

In conclusion, emotion, reward, and pleasure appear to be programmed to specific stimuli through experience and exposure. This programming involves certain brain structures as a neurodevelopmental process or in later life (Rahman, 2008). Paraphilias may emerge from these processes with disruption of normal psychosexual social communication and neural development.

Paraphilic disorders pose unique challenges to social scientists, clinicians, and the criminal justice system. Their classification has been molded by history, religion, culture, legislation, and social attitudes. The private nature of the majority of practices, associated embarrassment and the unlawful situations that bring them to attention make studies particularly challenging. Most studies are among offender groups and population prevalence is fraught with limitations. Proxy measures of interests or fantasies (e.g., pornography) may not apply to real-life situations. Paraphilias are also adaptive to technologies and globalization. Our limited knowledge of these disorders is an invitation to researchers of all fields to fill the large gaps in our understanding of sexual practice.

Abstract

The Swiss Johann Heinrich Pestalozzi (1746–1826) was one of the most distinctive writers of his time, and was already in his own lifetime regarded as one of the most famous pedagogs in Europe. He owed his reputation as a writer essentially to his best-selling novel *Lienhard und Gertrud* whose theme was the story of the education and cultivation of an entire village. He achieved his fame as a pedagog through his work in Stans (1799), Burgdorf (1800–03), and Yverdon (1804–25) where for 21 years he directed a teaching and educational institute in which children from all over Europe were taught. Pestalozzi's work deals with a wealth of subjects in the fields of general politics, social policy, constitutional law, jurisprudence, literature, anthropology, philosophy, pedagogy, and social education. His practical and literary commitment was directed against social injustice, oppression, exploitation, dependence, and the lack of political freedom, and against the poverty and neglect of children and adults. His ambition was to free the poor from powerlessness and to help them be able to secure their own subsistence, as well as to abolish the political and social conditions which caused this hardship. Pestalozzi's pedagogical authorship was rooted in social reality. In his active pedagogical work, he developed a theory and practice of a new teaching and training method whose principles were the ability to visualize, simplification, logical progression, and individualization. His method was aimed at the moral elementary education of the child and of the future adult, as well as at imparting the skills with which they would be able to secure their own subsistence.

Introduction

Johann Heinrich Pestalozzi was one of the most distinctive writers of his time, and was already regarded as one of the most famous pedagogs in Europe in his own lifetime. He owed his reputation as a writer essentially to his best-selling novel *Lienhard and Gertrud* (1781), and owed his fame as a pedagog to his work in Stans (1799), Burgdorf (1800–03) and in Yverdon (1804–25) where for 21 years he directed an institute in which children from all over Europe were educated.

Johann Heinrich Pestalozzi's work deals with a wealth of subjects in the fields of general politics, social policy, constitutional law, jurisprudence, literature, anthropology, philosophy, pedagogy, and social pedagogy, and it is documented in 30 volumes in the Critical Edition *Samtliche Werke und Briefe*, 15 of which have hitherto appeared (also available on CD-ROM).

Pestalozzi was, in both his personal and literary life, actively opposed to social injustice, oppression, exploitation, dependence, and lack of political freedom. His ambition was to free the poor and their children from powerlessness, to help them to be able to secure their own individual subsistence, as well as to abolish the very political conditions which caused this hardship. He constantly gave central importance in his work to social justice, the satisfaction of needs, ownership and work, domestic order, and basic needs for all, including children. The subjects he addressed were rooted in social reality. Pestalozzi reflected upon and analyzed the everyday life of the poor masses, the everyday life of children, and the everyday political life of his time.

The special form of this relation to reality Michel Soetard (1981) has convincingly called the 'Principle Reality.'

Life and Work

1746–99: Childhood, Youth, and Early Career

Family Origins and Childhood

Johann Heinrich Pestalozzi was born in Zurich on the 12 January 1746, the son of the surgeon Johann Baptist Pestalozzi and his wife Susanna, nee Hotz. At that time, Zurich was a center of European culture, a city state with an exclusive merchant and entrepreneurial aristocracy. The town was regarded as rich, with a small number of old families holding power in the city council. Neither his father's family nor his mother's – who originally came from the Zurich area where her father was a parish priest – belonged to this group. The married couple produced seven children in 9 years of marriage from which only three grew to maturity. When Pestalozzi – one of seven children – was 5 years old, his father died at the age of 33, leaving his mother to take care of four small children. In order to lead a bourgeois life in spite of the financial predicament, economizing, and making-do became a staple of their dismal everyday life. Pestalozzi had therefore to endure poverty. In the country at his grandfather's house in Höng, where his grandfather was a parish priest, he became acquainted early on with the miserable social condition of the provincial population which was to occupy him for a lifetime.

School and Studies

In Zurich, Pestalozzi – who had the civic rights – grew up with the sons of the patrician families whose carefree material situation was permanently laid out before his eyes. He enjoyed the schooling of a city dweller, and went to the city elementary school from 1751 to 1754; he was then a pupil from 1754 to 1763 at the Schola Abbatissana in Zurich, the Schola Carolina, and the Collegium Humanitatis (also in Zurich), the latter being a Latin school. After some initial difficulties he was

a good pupil, though because of his financial situation he was always an outsider because of his 'extra-ordinary carelessness and uncleanliness.' From 1763 to 1765 he studied at Zurich's theological college, the Carolinum. The appearance of an anonymous pamphlet he had co-written caused the abrupt end to his studies. It was clear to him in any case that he did not wish to become a priest.

In Zurich there were – following the example of other European countries – patriotic and physiocratic societies. From 1764, Pestalozzi belonged to the circle of patriots of the Helvetic Society. The Zurich scholars Bodmer and Breitinger in particular had their circle of influence here. The much-admired model was Rousseau. Republican works were read and written. It was in this context that Pestalozzi's first publications *Agis* (1766) and *Wünsche* (1766) appeared. In 1767, Pestalozzi began a short agricultural apprenticeship with the Bern physiocrat Tschiffeli.

Livelihood

In February 1769, Pestalozzi became a farmer in Müllingen and ran into heavy debt. On 30 September, he married *Anna Schulthess* (1738–1815), and on the 13 August 1770 their only child Hans Jakob, called Jaqueli (1770–1801), was born. Pestalozzi built a manor house, the 'Neuhof auf dem Birrfeld' which he moved into with his young family in 1771. Crop failure, bad purchases of land, and other mistakes led to failure and almost to financial ruin. In 1794, he founded an institution for the poor at the Neuhof. His initial interest was more entrepreneurial than pedagogical; in his *Neuhof-Schriften* (published in 1777), Pestalozzi accompanied his essays with a journalistic advertising campaign for support for his project. In his *Bitte an Menschen-freunde*, he successfully enlisted the support of, among others, Niklaus Emanuel Tscharner (1727–94), the chairman of the Bern Society for Economics. Pestalozzi discovered his interest in all things pedagogical during his time at the Neuhof, motivated by his interaction with the poor children of the Neuhof: "I saw how the overwhelming cruelty of self-interest constantly destroys the body and soul of almost – and I mean almost – all of these children." Pestalozzi's institution failed financially, but he was later to make use of his experiences in the field of national education.

In the middle of the Neuhof crisis, the political work about Zurich *Freyheit meiner Vaterstatt* (1799) – which remained unpublished – was written in which he lamented the wealth of the city and its devastating effects on the constitution and political culture of Zurich.

From 1780 to 1799: Livelihood as an Independent Writer

Out of the necessity of having to finance himself, Pestalozzi became a writer. In 1780 he published *Abendstunde eines Einsiedlers* whose theme is vating people: "Cultivating people toward the truth means cultivating their being and their nature toward a reassuring wisdom." Then he wrote the first part of *Lienhard und Gertrud*, which appeared in 1781. *Lienhard und Gertrud* is a pedagogical novel which its author broadened into a novelistic pedagogical text. The theme of the novel is the story of the education and cultivation of an entire village. With *Lienhard und Gertrud*, Pestalozzi wrote about a fictitious village which he called Bonnal in a novel showing both the development and the education of the characters. The subject of the novel is bound together by a kaleidoscope of multifaceted and fictitious stories of education, cultivation, and socialization.

In the second (1783) and third (1785) books, it becomes clear how many individual fates have been embroiled in the deplorable state of affairs in Bonnal for many years, and that it is thereby not only a question of individual error, but at the same time of failings which lie more deeply in the political structure. Only in the fourth book (1787) does it become possible to continue telling the story of Bonnal and to organize it structurally as a story of reform, with, of course, further novelistic twists and turns and subplots. The village as the scene of the action is increasingly abandoned. Paragraph by paragraph Pestalozzi outlines his ideas for new legislation, the distribution of land, jurisdiction, and the culture of debate and justice. The novel is therefore increasingly interrupted on the level of action and plot, becomes more difficult to read, and thus loses its original novelistic character. The literary code transforms into a politically discursive text. *Lienhard und Gertrud* became Pestalozzi's greatest literary success. Pestalozzi was soon to become known far beyond the Swiss borders, first of all not as a pedagog, but as a writer. The novel brought him the title of Honorary Citizen during the French Revolution.

In *Gesetzgebung und Kindermord* (written in 1780 and printed in 1783), Pestalozzi declared the prevailing legal practice throughout Europe of executing child-murderesses – mostly after extreme humiliation and torture – as inhuman. He mounted an emotive defense of a large number of child-murderesses, whom he viewed as innocent. To him, poor girls and women had the fundamental right to sexuality and marriage, to their children, to protection and support, and to recognition and help. The work was a plea against capital punishment.

In 1782, Pestalozzi published *Christoph und Else*, a novel of instruction, even a 'novel' for the novel *Lienhard und Gertrud*. It was to be used as a guide to how adults should read *Lienhard und Gertrud*. A peasant family talk together over 30 evenings about the plot, the theme, and the constellation of characters in *Lienhard und Gertrud*. On 26 August 1792, Pestalozzi was appointed an Honorary French Citizen and never renounced the honorary title in spite of all the criticism of the Terror, an action which aroused suspicion in conservative circles. The outcome of Pestalozzi's examination of the revolution was the work *Ja oder Nein?* (1793) in which he made the Ancien Régime responsible for the devastating outrages in Europe and thus justified the revolution, though at the same time he sharply denounced the revolutionary Terror.

In 1797, Pestalozzi's main philosophical work *Meine Nachforschungen über den Gang der Natur in der Entwicklung des Menschengeschlechts* appeared. The initial question was 'What am I, and what is mankind?' Pestalozzi expounded a natural state, a social state, and a moral state of humanity, and went on to discuss the individual human being as a 'work of himself,' a 'work of nature,' and a 'work of morality.'

In 1798, the revolution also reached Switzerland. For a short time, a Helvetic Republic was established. Pestalozzi became the editor of the 'Helvetisches Volksblatt' – the publication organ of the new Helvetic government – and at first worked on behalf of the government. He wrote texts, appeals, and pamphlets, as well as *Abhandlung über die Natur des*

Helvetischen Zehnden. Whereas the typical pamphlets on both sides at the time of the revolution constituted obvious works of political agitation in favor of one side or the other, Pestalozzi was a mediator who urged the often very hostile opposing groups toward agreement. He became a soother of passions in his pamphlets. Pestalozzi wanted to promote the unity of the Swiss in the crisis year of 1798, the unity between the poor and rich population, the unity of town and country, and the unity of the Inner-Swiss (Catholic) cantons and the majority Protestant cantons.

1799–1827 the Pedagog and Institute Director: From Stans to Yverdon

Stans

At the age of 53, Pestalozzi received a government commission to run an orphanage in Stans. From 7 December 1798 to 8 June 1799, he lived there together with a housekeeper and as many as 80 children by the end. His pedagogical work and his pedagogical writing were now supported by two pillars. The first was a love of children and a passion for his work. Pestalozzi made himself into the 'father' and 'mother' of all the children; he tried to transpose the notion of the great importance of satisfying basic needs. The second was that the fundamental principle of the 'method' – which was on the one hand an almost technocratic syllabic reading method – was at the same time elevated by the idea of an elementary method of moral education. From then on, Pestalozzi's elementary education and elementary method were central themes. The institute, however, came to a sudden end. Pestalozzi had to hand over the building to French soldiers returning from the Russian campaign for use as a hospital and leave the institute, an action which made him fall into deep depression and despair. During this time, he wrote his strongly influential work, the Stanser Brief (1799), which contained a passionate plea for the malleability of human beings, including, and indeed especially, for the malleability of poor, neglected children.

Burgdorf

Pestalozzi became a teacher in Burgdorf on 23 July 1799. The announcement of a schoolmasters' conference in Burgdorf Palace followed on the 24 October 1800. The appearance of *Wie Gertrud ihre Kinder lehrt* followed in 1801. In the first part, Pestalozzi reported on Stans in autobiographical form, on his first endeavors in Burgdorf, on his young colleagues, some of whom accompanied him for a considerably long time, and on how he conceived method, the unity of knowledge, ability, and feeling. Pestalozzi developed a research program which he continued in Yverdon and which aimed at developing suitable learning aids in the three directions which he soon named 'HeadHeartHand.' The principles of the new teaching method consisted of the ability to visualize, simplification, logical progression, and individualization. The method was aimed at developing the autonomy of the child, at creating an independent personality which could secure its own subsistence. From November 1802 to February 1803, Pestalozzi traveled to Paris as a member of the Consulta. He was, however, unable to push through his concept for national education there. In June 1804, the institute at Burgdorf was moved to Münchbuchsee, and at the end of August the opening of a subsidiary institute followed in Yverdon, a town in French-speaking Switzerland, and on the 6 July 1805, Münchbuchsee was closed.

From 1804 to 1825, Pestalozzi ran one of the largest European educational institutes of the time in the rooms of the palace at Yverdon in French Switzerland. Yverdon was an experimental school on the level of its teaching, education, and teacher training. In order to be able to disseminate the new knowledge acquired from the everyday pedagogical research, a printing works was set up specifically for this purpose. Pestalozzi, who until that time had always written his works alone, now published journals, teaching books, teaching material, discourses on teaching methods, appeals, and speeches with his colleagues. At the center of these works stood Pestalozzi's concept of an elementary education of people which could be applied to different teaching disciplines.

At the height of its impact in 1809, the institute had 150 pupils from 6 to 16 years old, 31 teachers and assistant teachers, and 40 young people as observers from all over Europe who wished to study Pestalozzi's method. Pestalozzi's concept of elementary teaching was already being followed ever more closely in Prussia, Spain, and many other countries. Pestalozzi's most important work from the Yverdon period is *An die Unschuld, den Ernst und den Edelmut meines Zeitalters und meines Vaterlands* (1815), a treatise in the form of an address in which Pestalozzi set out his program for life: "The beginning and the end of my policy is education." Pestalozzi analyzed the approach of the industrial age with its phenomena of concentration, mechanization, and standardization. Only in education did he see the means to prepare people for the Industrial Age. The work caused a great sensation and was a literary success.

The size of the staff and the differences of interest and opinion within the teaching body increasingly led to endless quarrels which finally caused the downfall of the institute. Pestalozzi left Yverdon embittered in 1825, and returned to the Neuhof.

In the last 2 years of his life, he wrote the works *Meine Lebensschicksale als Vorsteher meiner Erzie-hungsinstitute in Burgdorf und Iferten* (1826), the *Schwanengesang* (1826), and finally the *Langenthaler Rede*. During the crisis which industrialization and the reorganization of the states into large administrative states gave rise to, Pestalozzi saw a great opportunity for man to return to himself, and for his inner renewal by means of a comprehensive elementary education.

After a short illness, Pestalozzi died on 17 February 1827. On 19 February, he was buried near the Neuhof in the small village of Birr.

Critical Reception and Research Developments

The research literature on Johann Heinrich Pestalozzi's life and work, amply documented by the research papers and synopses of the Pestalozzi literature of the past 200 years, at first glance appears immensely extensive. This lies in the fact that Pestalozzi, in the history of (German-speaking) pedagogy and educational sciences, has without doubt experienced a considerable *impact* history which has admittedly only to a certain degree coincided with the *reception* history of his numerous written works. Above all, Pestalozzi's teaching method is

prescribed in many countries around the world and his best-known works have been translated into many languages. Should one follow the numerous publications up to the present, it becomes apparent that, whereas in the first half of the twentieth century the 'whole Pestalozzi' became the subject, individual or partial aspects began, however, to dominate more and more markedly within the framework of the differentiation of educational science and its adjacent sciences. In this way, the paradigm exchanges in educational science are mirrored in the respective cognition interests of analyses. If the Pestalozzi from the history of ideas took center stage in scientific literature in the middle of the twentieth century, the research controversy about the *political Pestalozzi* (Rang, 1967) was sparked off in the 1960s and 1970s. In the course of the 1970s with its far-reaching education and school reform, interest was then concentrated rather more on the practitioner and reformer. Within the research history, it furthermore became clear that after a very intensive, bibliographically broad and verifiable acceptance of Pestalozzi the politically reforming pedagog, the research in the 1980s stagnated; indeed the number of papers and studies about Pestalozzi fell off considerably. That only changed in 1996. Since then, the trend has been moving in the direction of an examination of the research into context and reception (the impact history) alongside biographical research using new scientific methods, aimed at producing a differentiated situating of the work as regards history and content. An important impetus comes from the work of the Pestalozzi Research Center which, dividing the work between the Pestalozzianum and the University of Zurich, is pushing forward with the Critical Edition, and publishes the *Neue Pestalozzi-Studien* and the *Neue Pestalozzi-Blätter*.

Pestalozzi's journalistic work is so diverse that it not only touches on areas of social and cultural practice as regards content, or even focuses on them explicitly as a central theme, but also represents groups of different discourse methods. In order to understand the work, interdisciplinary research is required; e.g., into rhetoric, eloquence and discourse, the socioaesthetic culture of sentimentalism, social history, the relationship between the written and the spoken, the problematic nature of text selection, the relationship between truth and fiction, the theory of femininity, and the ensuing mother cult of the eighteenth century.

EDITOR IN CHIEF BIOGRAPHY

James D. Wright received his bachelor's degree in philosophy from Purdue University in 1969, a master's degree in sociology from the University of Wisconsin in 1970, and his PhD in sociology from Wisconsin in 1973. His first academic appointment was at the University of Massachusetts, Amherst, where he was promoted to Associate Professor in 1976 and to Full Professor in 1979. Most of his 15 years at Massachusetts were spent as Director, Associate Director, or Director of Research in the Social and Demographic Institute.

Wright left Massachusetts for Tulane University in New Orleans in 1988 where he served as the Charles and Leo Favrot Professor of Human Relations in Tulane's Department of Sociology. He also enjoyed a courtesy appointment in the Tulane School of Public Health, Department of Biostatistics and Epidemiology. He left Tulane in 2001 to become the Provost's Distinguished Research Professor of Sociology at the University of Central Florida. In 2003, he was named as the Director of the University's Institute for Social and Behavioral Sciences and in 2013, was designated as a UCF Pegasus Professor, the University's highest faculty honor.

Wright was the Editor in Chief of the scholarly journal *Social Science Research* from 1978 until 2014. His previous editing experience also includes a 20-year stint as editor of the Aldine de Gruyter book series *Social Institutions and Social Change*, two editions of the *Handbook of Survey Research* (Academic Press, 1983; Emerald Publishing, 2010), and service on the editorial boards of numerous journals. He is the author of 21 books and scholarly monographs on topics ranging from homelessness to research methods to NASCAR, and he has published more than 300 journal articles, book chapters, reviews, essays, and polemics. Wright lives with his wife Christine Stewart and their multiple dogs and cats in Winter Springs, Florida, where in his spare time he likes to cook fancy meals for large crowds.

PREFACE TO THE FIRST EDITION

Large and ambitious works such as the present Encyclopedia depend on countless instances of input, cooperation, and contextual support. Therefore, the editors in chief would like to express their gratitude to several institutions and individuals. Our most general thanks go to our respective home institutions, the Center for Advanced Study in the Behavioral Sciences, Stanford, and the Max Planck Institute for Human Development, Berlin. We are certain that without the effective infrastructures of these institutions and the rich collegial networks and intellectual climate they provide, implementing this Encyclopedia in such a short amount of time would not have been possible. In this context, we also need to mention that due to the administrative budgets provided to the editors in chief by the publisher, the financial strains on our home institutions were minimal. Such a situation may be a rarity in the modern world of scientific publishing where publishers often press scholars and institutions into taking on larger and larger shares of the publication enterprise.

Aside from the more than 4000 authors, our deepest thanks goes to the editors of the 39 sections, to whom we delegated many decisions at various stages, who were primarily responsible for developing the lists of articles and authors, and who stood as the main gatekeepers of scientific quality for the entries in their sections. As a group, the section editors displayed remarkable energy, intelligence, and tolerance for the inevitable frustrations of tending large numbers of authors over a long period of time. Because of the brevity of the acknowledgment of the main editorial coproducers here, we alert the reader to the list published as part of the front matter and the description of their extensive work we offer in the Introduction. We would also like to mention that one of our highly esteemed section editors, Franz Weinert, died unexpectedly during the last phases of his editorial work. For people who had the pleasure of knowing Franz Weinert, it comes as no surprise that he completed his editorial duties without ever complaining about the difficult health conditions he was facing. He was a gentleman and a distinguished scholar.

The International Advisors also gave wise counsel on several designated occasions, and a number of these scholars represented on the International Advisory Board took more initiative — always helpful — than we had originally asked. The International Advisory Board was particularly helpful in the process of choosing section editors. Some of its members assisted us ably as we attempted to make the Encyclopedia as international as possible and also in dealing with special problems that are part of a large project with close timelines. Thus, we remember a few occasions where members of the International Advisory Board helped us with their substantive and social competence to deal with matters of editorial disagreements. Because of the overall quality, collaborative spirit, and professional responsibility of our section editors, these events were rare indeed, but dealing with them required masterful and accelerated input. We appreciate the collegiality that members of the Board displayed when called upon in these special circumstances.

In addition, and as described in the Introduction, there was a host of esteemed colleagues who gave us advice on numerous questions such as author and editor selection, organizational matters, topics for entries, content and quality of selected articles, substantive and methodological niches to be covered, as well as last-minute author replacements. The number of such individuals is large indeed, and most likely, significantly larger than the list presented below. There were too many short, but nevertheless significant collaborative encounters that we likely did not deposit into our long-term memory or written documentation. We apologize for such oversights.

In this spirit, we appreciate the advice given in the three planning meetings in Stanford, Uppsala, and Dölln/Berlin by the following scholars: Peter Behrens, Burton Clark, Gordon Clark, Lorraine Daston, Meinolf Dierkes, Jean-Emile Gombert, Torsten Husén, Gérard Jorland, Ali Kazancigil, Wolfgang Klein, Gardner Lindzey, Renate

Mayntz, Andrew Pettigrew, Denis Phillips, Marc Richelle, Ursula M. Staudinger, Piotr Sztompka, Eskil Wadensjö, Björn Wittrock, and Robert Zajonc.

We would like to extend special thanks to Laura Stoker, who pinch-hit for Nelson Polsby (section editor for Political Science) who was unable to attend the meeting of section editors in April 1998; and to Linda Woodhead, Senior Lecturer in Religious Studies, Lancaster University, who assisted David Martin with editorial work at all phases for the section on Religious Studies.

We also acknowledge the help of scholars who advised Smelser and Baltes at the stage of pulling together the entry lists, proposing authors, and occasionally reviewing the content and quality of articles submitted.

Smelser thanks: Jeffrey Banks, Peter Bickel, Edgar Borgatta, Charles Camic, Jennifer Chatman, Jean Cohen, Michael Dear, Pierre Ducrey, Eckart Ehlers, Sylvie Faucheux, Steven Guteman, Frank Furstenberg, Helga Haftendorn, Peter Katzenstein, David Laibson, Stephan Lauritzen, Douglas McAdam, Eleanor Maccoby, Phyllis Mack, Cora Marrett, Douglas Massey, Donald Melnick, Harvey Molotch, Lincoln Moses, James Peacock, Trond Petersen, Andrew Pettigrew, Alejandro Portes, Matilda Riley, István Rév, John Roberts, Dorothy Ross, Rob Sampson, Fritz Scharpf, Melvin Seeman, James Short, Fritz Stern, Carol Swain, Ann Swidler, Ken'ichi Tominaga, Charles Tilly, Wolfgang van den Daele, Sidney Verba, Margaret Weir, Thomas Weisner, and Jennifer Wolch.

Baltes is very grateful to: Nancy Andreasen, Gerhard Arminger, André-Jean Arnaud, Jens Asendorpf, Jan Assmann, Margret Baltes (deceased), Jürgen Baumert, Peter Behrens, Manfred Bierwisch, Niels Birbaumer, Peter Bloßfeld, Walter Borman, Robert F. Boruch, Mark Bouton, Michael Bratmann, David Buss, Shelley Chaiken, Lorraine Daston, Juan Delius, Marvin Dunnette, Georg Elwert, Helmut Fend, Hans Fischer, Peter Frensch, Alexandra M. Shavelson, Joan E. Sieber, Burton Singer, Wolf Singer, Edward Smith, Hans Spada, Günter Spur, Rolf Steyer, Michael Stolleis, José Juan Toharia, LeRoy B. Walters, Elke U. Weber, Peter Weingart, and Reiner Wimmer.

There was one more group that played a special role in the editorial review (see also Introduction). Baltes was assisted by a team of colleagues who provided expert input to the section editors and to him during final review: Gregor Bachmann, Alexandra M. Freund, Judith Glück, Wolfgang Klein, Olaf Köller, Shu-Chen Li, Ulman Lindenberger, Ursula M. Staudinger, and Christine Windbichler. Their expertise in helping us to ensure quality is gratefully acknowledged.

The day-to-day organizational work of the editors in chief occurred at their respective research centers — the Center for Advanced Study in the Behavioral Sciences and the Max Planck Institute for Human Development in Berlin. Smelser singles out Julie Schumacher, his main assistant in the project, for her organization of the meeting of section editors, and her superb coordination of the flow of correspondence and manuscripts over several years. She remained firm when the rest of us were faltering, and displayed the greatest efficiency, intelligence, and good cheer. Smelser also relied on periodic help from Leslie Lindzey, Kathleen Much, Jane Kolmodin, and Anne Carpinetti. Michelle Williams of the University of California, Berkeley, served as his main editorial assistant for nearly 2 years, going over all entry manuscripts from the standpoint of readability, and carrying a great part of the cross-referencing work; her judgment was always the best, and Smelser is forever indebted to her.

At the Max Planck Institute for Human Development, and aside from Julia Delius (see below), Baltes expresses his deeply felt thanks to the main secretarial staff in his office (Helga Kaiser, Romy Schlüter, Conor Toomey) who during the preparation of this Encyclopedia took on larger shares of responsibilities for other projects and occasionally helped out when the editorial office was overloaded. More directly involved in the day-to-day operation of the Encyclopedia was Penny Motley, who efficiently functioned as project secretary during the planning phase. During the main phases of the project, it was Yvonne Bennett who was responsible for secretarial and organizational matters. She deserves much applause for her superb and efficient help in the day-to-day running of the editorial office, making sure that all manuscripts and proofs were processed quickly, and also for assisting with the organization of various meetings. Not least, Baltes thanks the administrative office of the Max Planck Institute, and there especially Nina Körner and Karin Marschlich, for their competent work in managing the project budget, as well as Sabine Norfolk who handled most of the numerous fax

transmissions with ever present smiles and friendliness. Finally, in the Berlin editorial office, thanks are also due to Susannah Goss for her excellent work in translating individual articles into English.

Individual section editors wish to thank the following scholars who gave them substantive advice in their work: Richard Abel, Itty Abraham, John Ambler, Karen Anderson, Mitchell Ash, Alan Baddeley, Boris Baltes, Manfred Bierwisch, Michael Bittman, Sophie Bowlby, John Carson, Shelly Chaiken, Roger Chartier, François Chazel, Stewart Clegg, Carol Colby, Philip Converse, James Curran, Jerry Davis, Natalie Z. Section editors also thanked the following persons for their research assistance: Pamela Anderson, Susan Augir, Anja Berkes, Chantale Bousquet, Aida Bilalbegović, John Clark, Susanne Dengler, Kathrine Derbyshire, Annie Devinant, Casey B.K. Dominguez, Barbara Dorney, Elizabeth Dowling, Tracey L. Dowdeswell, Carolyn Dymond, Debbie Fitch, Susannah Goss, Verhan Henderson, Andrew Hostetler, Gudrun Klein, Heike Kubisch, Angie Lam, Ellen Lee, Valerie Lenhart, Kay Levine, Allison Lynn, Helena Maravilla, Carol B. Marley, Marion Maruschak, Michael McClelland, Rhonda Moats, Birgit Möller, Katja Neumann, Linda Peterson, Justin Powell, Paul Price, Xandra Rarden, Chris Reiter, Deborah Sadowski, Heidi Schulze, Heidi Sestrich, Keith Smith, Judith Thompson, Karen Varilla, Stuart Vizard, Danelle Winship.

It is difficult to single out one person as especially helpful. Despite the risks involved, we would like to highlight one person (see also Introduction). As shown in the front matter, beginning in the second year of the planning phase, Julia Delius served as our scientific editorial assistant. For our internal process of editorial review and management, Julia Delius was the mastermind of editorial coordination. Her work was simply outstanding.

Finally, we express our thanks to several individuals at Elsevier publishers whose work was both essential and helpful to us throughout. Barbara Barrett started the ball rolling for the entire Encyclopedia project, and was a master at negotiating out the fundamental arrangements at the beginning. Geraldine Billingham, as executive editor, also played an important role in the development of the project, as well as carrying the heavy responsibility for ensuring that all the financial and operational aspects of the project were realized. She executed this work with directness, skill, and tact. Angela Greenwell coordinated the editorial process with dexterity, calmness, and good judgment. Three persons were responsible for monitoring the progress of entries from Elsevier's side: Michael Lax for a time at the beginning; Jayne Harrison, who carried an overwhelming load of manuscripts month after month, and Helen Collins, who was responsible for the equally demanding job of shepherding the manuscripts through the entire production process. Ruth Glynn skillfully and imaginatively masterminded the development of the electronic version within Science Direct. We know how much the success of the Encyclopedia has depended on these individuals and their staffs, and our appreciation and admiration is here recorded.

Our expressions of gratitude and respect for the authors, section editors, reviewers, counselors, and editorial team, however, are not meant to distract from our own responsibilities as editors in chief. Let us hasten to add, therefore, that those whom we acknowledge deserve most of the credit but little of the blame for whatever shortcomings remain.

INTRODUCTION

Alan Sica's article in this encyclopedia observes, "The urge to systematize and rationalize both common and esoteric knowledge has been strongly and continuously in evidence for at least 2400 years in the West" (Sica, 2015). Sica dates the origins of this urge to Plato's nephew Speusippus, who took up the challenge of Plato's call for an *encyclopedia* (from Greek words meaning 'general education'), and traces the urge though Pliny the Elder, Vincent of Beauvois, Francis Bacon, Denis Diderot, and a great many others. Today, an encyclopedia is simply a self-contained reference work "with two aims: to include up-to-date knowledge about a particular discipline or group of disciplines and to make this knowledge conveniently accessible" (Smelser and Baltes, 2001). Such are the aspirations of the present work.

Histories of the concept of an encyclopedia are widely available and need not occupy us here. Those interested in where the *International Encyclopedia of the Social and Behavioral Sciences* (IESBS) fits into the long history of encyclopedias will do well to consult the Sica article quoted above or the Smelser–Baltes 'Introduction' to the first edition of this work.

This is the second edition (2/e) of the IESBS. Elsewhere, I acknowledge my immense debt to the editors of the first edition, Dr Neil Smelser and Dr Paul Baltes. Without their perspective and template to follow in assembling the second edition, this version would have scarcely been possible. The very thought of an encyclopedia covering *all* the social and behavioral sciences, one that drew on scholars from *all* corners of the globe, is itself so audacious that one would hesitate even to begin without a pretty detailed road map to the terrain.

On the occasion of the publication of Robert E.L. Faris's widely acclaimed *Handbook of Modern Sociology*, Joseph Gittler was moved to ask, "With the plethora of new handbooks, reviews, and compendia in sociology, one wonders whether there is a need for yet another one." That question was posed almost 50 years ago; the ensuing half-century has been marked, as Sica says, by "an avalanche of reference materials the likes of which had never been seen in libraries prior to about 2000." So readers and critics are within their rights to ask: Why a second edition? Why now?

The first edition (1/e) was reviewed in *Contemporary Psychology* as "the largest corpus of knowledge about the social and behavioral sciences in existence" (Park, 2004). According to readily available data sources, IESBS 1/e has been cited nearly 6000 times in subsequent scholarly literature and has an h-index ($h = 24$) that would be the envy of many full professors. Citations are only one measure of impact, of course, and probably not the most important measure for a basic reference work intended more for students and a general audience than for practicing professionals. In addition to the thousands of scholarly citations, items from IESBS 1/e were 'hit' almost two *million* times on Science Direct between online publication in November 2002 and August 2014 — two million instances where IESBS 1/e was likely consulted as a basic reference source, to get quickly up to speed in a new area of research or to provide background for a paper or project, or just to satisfy a reader's curiosity. The first edition, in short, emerged soon after publication as a go-to reference work throughout the social and behavioral sciences. Michael Shanahan referred to the first edition as "the atomic bomb of reference works." It was thus an easy conclusion that the work had sufficient value to keep it alive and current.

In reading selected articles from the first edition, however, I was taken aback by how much and how quickly they had aged. The first articles I looked at were those pertinent to my own areas of research and in nearly every case, there was important recent work that I felt needed to be discussed. With the assistance of colleagues in other areas of the social and behavioral sciences, it became obvious that this was a general problem. To be sure, much of the material in 1/e has enduring value; indeed, roughly half the articles in 2/e are updated and revised items from the first edition. Still, it is sobering to realize just how quickly the frontiers of social science

knowledge shift and thus how quickly a basic reference source becomes dated. I am certain there are articles in the current edition that are already in need of some updating.

Smelser and Baltes enumerated six criteria that guided their decisions about what to include and what to leave out. The criteria are as follows:

1. secure knowledge, realizing that security of knowledge is a dynamic and relative term,
2. knowledge with balance and comprehensiveness,
3. knowledge that is integrative rather than fragmented,
4. knowledge that places the evidence into historical and theoretical context,
5. knowledge that highlights connections between topics and fields, and
6. knowledge that combines, where possible, theory and practice.

I would like to say I have followed these same criteria in determining the content of 2/e, but all six criteria have proved problematic in one or another way and thus deserve some comment in light of the present work:

1. What is secure knowledge today is apt to be recognized as wrong tomorrow. Many of our requests for updates to 1/e articles generated some response to the effect, "All of this is completely obsolete. We need to write a new entry from scratch." One would expect this to be true of areas of research such as behavioral genetics, say, or cognitive neuroscience or other fast-moving scientific fields, but it also turns out to be true of archaeology, history, and philosophy. The leading edge of research in *every* discipline threatens received wisdom; those who content themselves with received wisdom ('secure knowledge') will quickly find themselves behind the times. So our charge to authors was to focus less on the 'secure knowledge' in their respective fields and more on the cutting edge — the new perspectives, methods, findings, and issues that will animate social and behavioral science research in the coming decade.
2. Throughout the social sciences, the distinction between theory and ideology is sometimes difficult to discern, and so too the distinction between applied research and community or political activism. We need not invoke Max Weber's conclusions about the impossibility of a truly value-free social science to understand that ideological undertones and political preferences can often be detected in social science research work; sometimes, they are quite explicit. Nor is it much of a surprise to learn that many social scientists struggle, not always successfully, to distinguish between what they want the world to be and what the world in fact is. Such struggles are part of the process by which knowledge develops and are thus in evidence in many of the 2/e articles. It would be unwise to enforce by editorial fiat a consensus on issues that the social sciences themselves have yet to resolve.
3. The fragmentation of knowledge *across* disciplines is far more serious that the fragmentation of knowledge *within* them, although the latter is a problem as well. Many well-informed sociologists, for example, take pride in reading widely and can speak with some authority about what is going on in the field, even in areas of sociology that do not directly concern them. I assume this is also true of the other social and behavioral science disciplines and areas. But rare is the sociologist who is cognizant of work being done, say, in social geography *even when*, as is often the case, the fundamental problems, theoretical issues, and methodological approaches are similar. This is a widespread problem across the disciplines: The evolutionary psychologists do not know as much as they should about what the anthropologists are doing; the economists ignore a lot of pertinent work in sociology and political science; etc. For better or worse, disciplinary differentiation is an inherent element in the process of knowledge development and discovery, so this is a reality to be faced, not a problem to be solved. We dealt with this reality mainly in two ways: (1) Authors were encouraged wherever possible to think across rather than strictly within their disciplines. (2) Calling relevant work done in other disciplines to the reader's attention was a guiding principle for the choice of cross-references for each article.
4. Social-constructionist theories of knowledge would argue that knowledge does not become knowledge until it is placed in historical, cultural, social, political, and theoretical context. As put very simply and succinctly in the opening line of the famous text by Berger and Luckmann, "reality is socially constructed" (1966: 1). This is no less true of social science knowledge than knowledge in any other realm. Unfortunately, a great deal of what we think of as social science knowledge is based on biased samples of WEIRD people — that is, Western, Educated, Industrialized, Rich, and Democratic (Henrich et al., 2010). (The same point has, of course, been made by many others.) The WEIRD, thus defined, represent a rather exotic minority group judged by world standards, and the challenge for IESBS 2/e was therefore twofold: (1) to recruit non-WEIRD editors and authors where possible; and (2) to persuade all authors to incorporate comparative, cross-cultural, and

international themes and perspectives wherever it was possible to do so. This effort was more effective in some sections than in others. Moving away from nation-specific literature, themes, and results to a truly *international* (the I in IESBS) account of the social and behavioral sciences was an ever-present *desideratum* in my discussions with editors and authors.

Alas, an emphasis on cross-culturalism often brings to light that everything, or nearly everything, seems to vary by culture, subgroup, ethnicity or nation, and at that point the question arises whether social science generalization is even possible. Are there universals that cross all social groupings? Or does social science dissolve into a mist of group-specific particularities that adduce no general principles? That hardly seems desirable. Yet myopic and ethnocentric fixations on one's own society or culture are scarcely to be encouraged either.

The worst offenders in this regard tend to be social scientists from the USA (and from the West more generally), who, of course, also comprise the largest share of editors and authors for IESBS 2/e. True, as with greenhouse gases, the USA (and the West) also produce the largest share of the world's science, social and otherwise, and so it is inevitable that they also represent the largest share of IESBS 2/e contributors. The Swedish social anthropologist Ulf Hannerz wrote about this very issue in his marvelous essay, "Editing Anthropology" (Hannerz, 2010). Hannerz quotes a Canadian anthropologist who said of the "neighborly presence" of US anthropology that it was like being "in bed with the elephant." The same is true of most or all of the disciplines covered in this work. But then in a passage remarkable for both its insight and its generosity, Hannerz remarks, "No doubt tensions and conflicts may arise out of this situation, but perhaps it is better to understand that the elephant cannot help being an elephant, and that it makes sense for it, in its habitat, to behave in elephantine ways. A well-trained elephant, too, can do a lot of good, such as in carrying heavy loads." So if the elephant that is Western social and behavioral science has been pressed to carry the heavier load in these pages, that is, the price to be paid for being an elephant in the first place.

The larger issue here is that the social and behavioral sciences, which were largely birthed in the West, in Europe and the United States, mainly address a trans-Atlantic scientific dialogue, a dialogue that is carried out almost exclusively in English. Indeed, throughout much of the world, a scientist's stature is indexed in part by his or her success in publishing in English. Publications in the native language are simply *assumed* to be inferior. The main exceptions, tellingly, are French and German social scientists whose native-language publications are valorized. A Dutch or Portuguese or Hungarian social scientist who only published in the native language would be seriously punished in merit and tenure reviews. Elsevier's citation database Scopus *requires* English-language abstracts before a journal will even be considered for inclusion. And English (with American spellings) is likewise the official language of this encyclopedia. No resources were made available to get articles submitted in other languages translated (although several such articles were submitted). Inevitably, this biases the encyclopedia's coverage in favor of social science addressed to the trans-Atlantic dialogue. Consequently, a great deal of excellent social science published in Spanish, or Mandarin, or Farsi, or any of the other world languages, is overlooked.

That said, steps were taken to improve the internationalism of the encyclopedia's coverage throughout the 4 years of its development. To begin, I sought area and section editors from around the globe and urged them whenever possible to seek international (vs strictly Western) authors. Articles were often returned to their authors with explicit instructions to add international coverage. And when all efforts failed and we ended up with articles that were unmistakably restricted to a single nation in their coverage (frequently but not always, this was the US), I indicated the national focus in the article subtitle. Still, a great deal more WEIRD social and behavioral science remains in these pages than would be desirable in an *international* encyclopedia. In a later section, I give the national breakdown of everyone involved in this project.

5. An encyclopedia that "highlights connections between topics and fields" is easier to envision than to accomplish. Criterion (3) above speaks to the disciplinary fragmentation of our social science knowledge. William Easterly, the NYU economist, has written about the 'tyranny of experts' but the tyranny of the disciplines is an equal problem, a tyranny sanctified by the very academic structure of the modern university, where the separate and often warring colleges are each comprised of assorted departments, the latter representing basic academic disciplines. Interdisciplinary programs are almost invariably relegated to various centers, institutes, or specialized research laboratories — in short, to the periphery of the university's power structure. And while everyone *says* they want to encourage multi- and interdisciplinarity, very little is done to make that happen. Instead, departments remain as the fundamental unit of academic organization.

   Hortatory admonitions to editors and authors have made IESBS 2/e somewhat more interdisciplinary than its several predecessors, but in the end, the disciplinary emphasis in many of our articles would be hard

to overlook. Still, there are many sections of the work that were clearly developed with interdisciplinarity in mind and in which one finds interdisciplinary social science at its current best: environmental and ecological sciences; health; life course; sexuality; GLBT studies; public policy; evolutionary sciences; war, peace, violence, and conflict; and genetics, behavior, history, and society are a few sections that come immediately to mind.

I am particularly pleased with the extensive coverage given in 2/e to the interactions between the biological and social sciences. Harry Whitaker once remarked in a private e-mail that "we are all witnesses to the marriage of biology and the social sciences." Many of the articles found here are offspring of that marriage. And those articles leave little doubt that the future offspring of this marriage will be among the most exciting and insightful social science products of the coming decade.

The social sciences once resisted everything biological as rank reductionism; in addition, the social scientists have always feared that a mature and complete biology would eventually drive us out of business. Articles included in IESBS 2/e make it clear that 'nature' versus 'nurture' was the wrong question from the very beginning, that what we need to understand is how biological inheritance and social and cultural forces *interact* to produce individual and collective outcomes. This is where a lot of the interesting action in the social sciences is going to be in the coming years.

6. The coverage of the practical or applied sides of the various disciplines has been increased in this edition, so the applied content of 2/e certainly exceeds that of its predecessor. New to this edition is the entire section on applied social and behavioral sciences; also new is our large section on social work and the separate section on applied, industrial and organizational psychology. But as Sara Strickhouser and I say in our article on the history of applied social research, "The history of 'applied social science' is indeed the history of the social sciences themselves" (Strickhouser and Wright, 2015). All of the social sciences in their modern form were birthed in the post-Enlightenment effort to understand why people, their institutions and society as a whole were as they were — why greed was more visible than generosity, why oppression was more common than freedom, why inequalities of various sorts characterized every social institution. To the founders of the disciplines, the modern distinction between basic and applied scientific concerns would have seemed meaningless, as indeed it was.

The Planning Phase and Editorial Structure

Elsevier's original acquisitions editor for this project, Scott Bentley, discussed the broad outlines of our attack on IESBS 2/e with me in a series of phone calls in the early months of 2010. By May 2010, certain of these outlines had come into sharp relief. There would be a single editor in chief with a tier of 'responsible lieutenants' to assist. These lieutenants started out as advisory editors but soon morphed into the 10 area editors in the final editorial structure. Each area editor would in turn oversee various sections and each section would have its own editor or editors. The original plan was that the area editors would each be responsible for approximately 400 articles and each section editor responsible for about 100 articles, so that no one would have an excessive amount of work compared to everyone else. In the end, however, some sections required more articles and others fewer, so the areas vary from fewer than 300 to more than 600 articles, and the sections vary from fewer than 30 articles to well more than 200.

Prior to my first discussions with Scott Bentley, Elsevier had commissioned about 20 'market surveys,' roughly half from professional librarians and the other half from academics, each focused on 'what was right and what was wrong' with the first edition. The most insistent demand that surfaced was for a fully electronic, computer-searchable work either in addition to or instead of a print version. In the end, both an e-version and a print version are being made available. But there were also consistent concerns expressed about spotty coverage of some areas: no coverage of social work to speak of; inadequate coverage of accounting, marketing, and business; no separate section of criminology; haphazard coverage of applied topics and concerns; and so on. And there were the predictable concerns about undue Western domination of the work.

Working from the 1/e Table of Contents and this stack of 20 surveys, I tinkered for a few months with how best to expand coverage to address the concerns our reviewers had expressed; the result was (more or less) the editorial structure shown elsewhere in the front matter of this work. Thus, the 53 sections of 2/e are basically the 39 sections of the first edition plus sections that were added to cover important emerging areas of research interest (e.g., gay, lesbian, bisexual, and transsexual studies) or to provide deeper coverage of disciplines and subdisciplines that the first edition treated lightly if at all (applied social and behavioral sciences, social work). A

few of the first edition sections were eliminated entirely: specifically, integrative concepts and issues (something of a catch-all category for 1/e articles that were highly interdisciplinary or simply did not fit anywhere else) and gender studies (gender is now so thoroughly integrated into the research and thinking of all the social and behavioral science disciplines and subdisciplines that a separate section was unnecessary and somewhat retrograde). Others were altered or expanded in significant ways (organizational and management studies, for example, became the second edition section on management, organizations, business, marketing and finance; expressive forms evolved into the 2/e section on culture and the arts; linguistics was subdivided into three separate sections; etc.) And some subdisciplinary areas that were part of other sections in the first edition were given their own sections in the second (life course studies; sexuality; criminology; labor studies; and war, peace, violence, and conflict are the most prominent examples), just to ensure adequate coverage.

The Introduction to 1/e (Smelser and Baltes, 2001) discusses at great length the intellectual architecture of the first edition and its evolution; the agonizing decisions about rules for the biographical articles; whether to organize the work by discipline, by concept, by an a priori taxonomy of social science knowledge, or in some other manner; and related structural matters. What resulted in 1/e was something of a hybrid model with some sections clearly representing specific disciplines, others representing 'overarching topics,' still others representing 'intersecting fields,' and so on. My task was far less challenging: I thought the architecture of the first edition served its purposes admirably and so I adopted it wholesale for the second edition, with the small modifications noted above.

While each of the 53 sections of 2/e has some more or less obvious justifying logic or substantive or disciplinary coherence, their arrangement into the 10 areas of the second edition does not. As already indicated, decisions about what sections to include and exclude were made very early in the development of the second edition, based on what was in the first edition, what Elsevier's marketing surveys suggested as significant lacunae, and my own sense of things. The arrangement of the sections into areas came later and was dictated largely by the interests and expertise of those who had been persuaded to sign onto the enterprise. Thus, all the Linguistics sections are in Area Five along with the cognitive and neuroscience sections because Harry Whitaker at Northern Michigan University had been a linguist first, a neuroscientist second, and a historian of psychology third. Likewise, Area Eight contains its seemingly chaotic hodgepodge of evolutionary sciences, genetics, religious studies, science and technology studies, and law because these happen to be the fields of interest of the redoubtable Barbara Prainsack of King's College, London, whose editorial talents are as deep as her interests are broad. Simplifying only slightly, section editors were chosen for their substantive expertise in particular areas of research (as well as their international or cultural 'range'); the plan was that section editors would review each of their articles for completeness of coverage, currency, fairness, and the like. In contrast, area editors were chosen for their breadth of interest and knowledge spanning multiple sections – people who by nature, experience, and training would be good at seeing the big picture. The role of the area editors was to assure that the articles were at least modestly international and interdisciplinary and formed some sort of coherent whole.

As laid out in an early e-mail to one of the area editors, "In my mind, Advisory [Area] Editors are generalists and Section Editors are content specialists. The Section Editors need to bring breadth of knowledge to their responsibilities, of course, but the primary job requirement is expert understanding of the particular field or section. We need section editors who can commission pieces that adequately review past developments in the subject area, but who can also shape their portfolios to identify major unanswered questions and new research developments." This was the general model followed throughout the recruitment process.

The approach just sketched inevitably left a residual area made of up sections that none of the other area editors were willing or able to claim. That proved to be Area Ten. A very large number of scholars from various disciplines and world regions were approached about serving as the Area Ten Editor. All demurred until I approached Martin Bulmer of the University of Surrey, who served the project for about a year but was unable to continue and subsequently left the Board. So for the final year of the project, the editing of Area Ten was done mainly by me.

The online subject classification for IESBS 1/e did not correspond precisely to the sections of the first edition; the subject classifications listed articles by broad general topic regardless of which 1/e section developed them. So for the first year or so, my assistants and I labored to assign every 1/e topic to one of the 53 2/e sections. With 53 sections to populate with articles and about 4000 articles to classify, the process of assigning articles to unique sections occupied huge amounts of time and generated endlessly complicated spreadsheets. (After about a year of this, a document surfaced in the Elsevier archives that showed exactly where each 1/e article had originated.)

Along with populating the 2/e sections with articles, searching for area and section editors occupied a major part of the early going. The original idea was to identify the 10 area editors first and then enlist them in the

search for their section editors, but in fact, these processes were simultaneous and were about half-completed when the two planning meetings were held: the first in San Diego on 19 and 20 May 2011; the second in London on 5–7 June 2011. Although not part of the plan, the first meeting was mostly attended by area editors and the second, by section editors.

The agenda for both meetings was largely identical: achieve clarity on the respective roles of the various editors; solicit advice on filling the unfilled editorial slots; get buy-in on the project *mantra* (internationalism, interdisciplinarity, inclusiveness!); explain the relationship between the first and second editions (e.g., that all 1/e authors would be offered the opportunity to update their articles); explain the process of assigning articles to sections; and the like. In almost all cases, consensus was quickly forthcoming.

The largest substantive change in the second edition is the treatment of psychology. (Whether measured by students, practitioners, professors or programs, psychology is the largest of the social and behavioral sciences.) In the first edition, the whole of psychology was contained within four large sections: clinical and applied psychology; developmental, social, personality, and motivational psychology; cognitive psychology and cognitive science; and behavioral and cognitive neuroscience. Cognitive science and neuroscience are, of course, rapidly growing sectors of the psychological discipline and it seemed appropriate to devote an entire area of the second edition to them. This area contained seven separate sections (three of them devoted to linguistics). And the 'softer' psychological sciences were placed in a separate area comprised of eight sections (including psychiatry and social work). These changes were made to assure that 2/e had adequate coverage of the entire psychological enterprise (a concern that was raised in some of the reviews of 1/e).

The structure of the editorial team was developed to serve two purposes: first, to divide up the labor into manageable parts; and secondly, to assure that every article in the final product would be reviewed by at least three scholars: the respective section editor, area editor, and the editor in chief. Since we were all aware of one another's identities throughout, the review process was not blinded, but every article in this work has been thoroughly peer-reviewed and vetted. In many cases, these articles have been through four, five, six, or even more revisions before being accepted for inclusion in the work.

Recruiting Editors and Authors

IESBS 2/e faced two different recruiting tasks: recruiting editors and recruiting authors. As indicated elsewhere, the original plan was that I would recruit area editors largely from my own personal networks and they in turn would recruit their section editors. In practice, the process was much more convoluted. First off, many of my 'first choice' candidates were hesitant to involve themselves in such a daunting and ambitious project. In some cases, an initial agreement to come aboard was followed a few weeks or months later by withdrawal as the true scope of work came into sharper focus. Some people that I tried to recruit as area editors demurred but agreed to serve as section editors; in other cases, candidates for area editors were nominated by section editors. In a couple of cases, there was a complete team of section editors prior to the successful recruitment of a corresponding area editor. And so on. The process of assembling an editorial team for the project was by no means linear.

Personal networks – mine and those of the people I persuaded to sign on – were the largest single source of ideas for other editors, by far. But personal networks tend to follow disciplinary and national lines and become rather quickly exhausted. In selecting both editors and authors, it was of course essential that all relevant perspectives be covered and that the breadth of fields was adequately represented. So other sources of ideas were tapped: the expertise of the Major Reference Works team at Elsevier; editorial boards of leading journals in the respective fields; Google Scholar citation counts; the knowledge and networks of people who had been involved in preparing the first edition – basically, anywhere names of top scholars in particular areas could be located. I did not keep systematic track of the number of people approached, much less of the outcomes; but in reviewing my e-mail archives from the early period of the project, I probably asked (on average) somewhere between six and eight prospects before I found someone to agree (an average that was highly variable across the areas and sections).

In the initial plan, area editors would recruit their own section editors and the section editors would in turn recruit their own authors, but the reality was again different. Inevitably, my negotiations with prospective editors (both types) would often result in a declination of the editorial role but an offer to write an article on a particular topic (or topics), offers I readily accepted. So in some cases, I had committed authors of particular articles well before I had the corresponding section or area editor in place. And many of the section editors likewise leaned on their area editors and on me for author suggestions, contacts, and outreach. So all the editors

were involved in locating willing authors (and not coincidentally, in making suggestions for articles to be included in the final work).

No one was asked to keep precise statistics on how many authors were sought before an agreeable author was found. My sense is that the 2/e editors had a somewhat tougher time with this than the 1/e editors had (but on the other hand, the 2/e editors had all the 1/e authors to work with, which Smelser and Baltes certainly did not have). The 1/e editors report that about 60% of those invited to write articles agreed to do so on the first 'ask' (with equivalent success rates in each subsequent 'ask'). In 2/e (or so I would guess), the success rate was probably closer to 50% and possibly even lower. They also report that something in excess of 90% of those who agreed to write for 1/e in fact contributed "acceptable entries in time to be included…" In the 2/e case, we found ourselves still soliciting authors within a few weeks of the submission deadline and some dozens of authors pulled out of the project at the last minute. Still, when all the dust settled, there were just about 800 articles planned for both editions that never materialized and both editions ended up with just fewer than 4000 articles. Perhaps these are 'natural limits' for a work of this sort.

Biographies*

In the Introduction to 1/e, Smelser and Baltes provided a short history of and rationale for the decision to include a limited number of biographical articles (150 of them, to be exact). This was evidently a controversial and contested decision since some of those associated with 1/e felt that biographical articles had no place in an encyclopedia focused on substantive knowledge (versus the personalities of those who produced it). As Newton said (paraphrasing a passage from Bernard of Chartres), "If I have seen further, it is by standing on the shoulders of giants" (a passage made famous among social scientists by Robert K. Merton's *On the Shoulders of Giants* (1965)). In other words, discovery is only possible because its discoverer is able to refer to knowledge already gathered and accumulated by his or her predecessors; and since all discoveries – small and large, substantial and minor – contribute to the production and accumulation of knowledge, singling out particular scholars for special attention would be both pointless and invidious.

This position, although understandable, was abandoned in the first edition and remains so in the second, largely because it is not possible to understand the social sciences without knowing the individuals who contributed to it. C. Wright Mills once defined the sociological imagination as the intersection of biography and history (Mills, 1959). To know the social sciences therefore requires biographical and historical knowledge. The social sciences are distinguished from the physical and biological sciences in the way they produce knowledge because individual human beings, including social scientists, invest meaning in their actions. Only through understanding the meaning that individuals give to their actions are social scientists able to provide explanations of human behavior and its outcomes. And what applies to social action in general applies to the production of social science knowledge as well. It thus makes sense to include biographical accounts of social science personages who have been particularly distinguished in making sense of human action and have in turn made major contributions to social science knowledge. To acknowledge individual social scientists with biographical articles is also to acknowledge their special and particular insights.

Once the decision was made to include biographies in 1/e, the next major decision was whom to include and whom to leave out. Two arbitrary but defensible principles governed these decisions: (1) the total number of biographies was not to exceed 150 (chosen because it seemed like a manageable number) and (2) only biographies of the dead would be included. The 1/e section editor for biographies, Karl Ulrich Mayer, consulted handbooks and encyclopedias, asked other section editors to name and rank the most important names in their respective disciplines, ran citation checks, and finally submitted a consolidated list to various experts for review. This resulted in some additions and some deletions and in the end 147 biographies made it into the first edition.

Instructions to authors writing these biographies directed them to include "a brief sketch of the major dates and events in the life of the biographee," to describe "the major contours of the [person's] substantive contribution," and to highlight the "importance and relevance of the biographee's work for the social and behavioral sciences." Largely the same instructions were given to 2/e biographers.

The selection criteria for 2/e were very different. First, on the reasoning that well-done biographies of leading figures is one of the things that draw readers to a work such as this, the total number of biographies was

* My thanks to Andreas Hess for drafting this section of the Introduction.

increased by more than 100 (to just over 250). In a major departure from 1/e, much of the increase is made up of biographies of the living. The 1/e restriction that excluded living persons resulted in anomalies that we thought needed to be addressed. As life expectancy has expanded in the twentieth and twenty-first centuries, so have the life spans of social scientists. Claude Levi-Strauss, to cite one obvious example, lived to the age of 101 years. When 1/e was published, he was in his 90s, was widely cited, was recognized universally as a modern classic, indeed a genius, of social anthropology – and yet, owing simply to his longevity, he was not included in the 1/e biographies. Biographies of, for example, the economist Herbert Simon, the political economist Albert O. Hirschman, the sociologist and philosopher Jürgen Habermas, and the linguist Noam Chomsky were all excluded for the same reason; indeed, Habermas and Chomsky still live as this is being written (Fall, 2014). In all these cases, the major works had been produced decades earlier, their major imprints on the social and behavioral sciences were already evident, their eventual inclusion in works such as this was inevitable. Are readers to be deprived of accounts of their lives, times, and contributions just because they have survived into deep old age?

Once the decision was made to include biographies of the living, however, it was not always easy to decide who among the living merited inclusion. Often the editors had to make decisions on a case-by-case basis, frequently in extended consultation with colleagues or experts in the field. Criteria used to make these decisions were whether the potential biographee had a reputation beyond one culture, nation, or language group; whether there was a record of sustained production over several decades; and whether there was an impact beyond the confines of a single discipline. These criteria reduced our list of suggested biographees considerably. Early lists of candidates numbered as many as 200 new names (in addition to the 147 biographies included in 1/e). In the end, as noted earlier, somewhat more than 100 new names were added.

In a few cases, persons were included that arguably did not satisfy our inclusion criteria. One such is Raul Hilberg, who became famous mainly for having written one very important book, *The Destruction of the European Jews* (1961). Hilberg's book is still regarded as the seminal work in Holocaust studies, a field of research that came to prominence much later; we felt that his signal contributions to Holocaust studies merited a biographical article. Much the same could be said, perhaps, of André Gorz, a well-known social theorist from France, and Albert Memmi, whose work is on colonialism, anticolonialism, and racism. These and other examples could and probably will raise questions about the porousness of our criteria. Whether we were right in giving 'trespassers' their space is open to debate. In any case, whether Hilberg, Gorz, Memmi, and others do or do not merit their biographies is for readers, not us, to decide.

Other important changes in the 2/e biographies section include, first, a conscious effort to attain a better gender balance, including more women both as biographees and as authors; and second, expanding the biographies both geographically and culturally. In the end we made some inroads in both respects but fell short of our internal goals. One of the main reasons for this is that any encyclopedia must, in the first instance, be true to the disciplines it represents. This means being true to the real status of important players, their networks and disciplinary power relations, and their academic capital in their respective fields and beyond. Change in these respects has been noticeable; certainly, the growth of the social sciences in Asia has been remarkable; and in most disciplines, the proportional presence of women has increased. But modest change in the right direction does not a revolution make. Too many nonwhite, non-Western, and nonmale practitioners are still being left out on the disciplinary peripheries and are not fully represented – not in their home disciplines and not in our encyclopedia either.

We state this fact with regret. In many cases, the limiting factor is not excellence but simple visibility. Being part of the trans-Atlantic social science dialogue and engaging this dialog mainly in English translates into more visibility, as discussed earlier. This gets a scholar on the radar screen. Equally excellent work engaging other intellectual dialogues in languages other than English does not. A great many outstanding scholars have thus gone unrecognized in 2/e for precisely this reason. That being said, strenuous efforts were made to make the 2/e biographies more inclusive. Among those included are the Argentinean educationalist Sarmiento, the Brazilian sociologist Cardoso, and the Japanese political scientist Maruyama, to name just a few. This is, however, 'just a few' of the many dozens of prominent social and behavioral scientists 'out there' whom we would have included had we been given more time and more resources (to get non-English works translated, for example). We do feel that we have made some important inroads and beg the reader's understanding of the limits within which we worked. We can only hope that the next edition will strive for more inclusiveness and better representation than we were able to achieve.

Another entirely new feature in the 2/e biographies is the series of 'collective biographies.' In many instances, the intellectual lives of individuals who work in research groups intersect and form a network that makes the

entire group (or paradigm) successful. Examples include articles on the Durkheimians, the Annales School, the Frankfurt School, and several others.

As indicated earlier, instructions to authors were changed little from 1/e. All authors were asked (1) to include the most important biographical facts (country of origin, generation, education, influences, other formative experiences, networks, etc.); (2) to list the most important output (discoveries, publications, etc.) and to briefly discuss the subject matter and content of the most important publications or discoveries; (3) to look at the lasting impact of the person and his or her work (if possible, beyond just one discipline, language group, or culture); and (4) to provide a bibliography of primary and secondary sources related to the biographee and his or her work. Most authors stuck to these guidelines.

Finally, we state for the record that there are a number of important social and behavioral scientists that we would have liked to include but for whom we were unable to find a proper biographer. The search for biographers went on for nearly 4 years. In many cases, our first-choice author agreed at once, but in other cases, we approached four, five, or even more people before an agreeable author was found. And in about two dozen cases, no such author was ever found, with the result that a deserving person's biography had to be dropped. Forgoing a case-by-case discussion of these deletions, let it be simply noted that this is why we have not included biographies of people such as Amartya Sen, the economist and social philosopher; Raymond Boudon, the French sociologist; Ronald Dworkin, the legal theorist; Avishai Margalit, the philosopher; or a collective article for the British Marxist historians (Eric Hobsbawm, E.P. Thompson, Christopher Hill, and Perry Anderson). Perhaps our most regrettable omission is Neil Smelser himself, for whom no biographer could be found despite at least a dozen attempts. (Paul Baltes's biography is included.) Neil is one of the giants on whose shoulders we all stand.

Redundancy

I mentioned earlier that in the beginning of the project, there was no 'map' linking each of the 1/e articles to its respective 1/e Section. Our efforts to create such a map invariably bogged down every time we hit an article that could plausibly belong to any of several sections, which was often. Obviously, it would have been possible to force every article into a 2/e section, but at the time it seemed advisable to involve the editors themselves in these decisions. So on numerous occasions, I distributed lists of 'orphaned' articles (articles for which no home had yet been designated) to the area and section editors, asking for foster parents to volunteer. Eventually, of course, every article found a home, but at a relatively late date in the process, I became aware that a few dozen articles had found more than one home. That is, some of the editors adopted articles without filing the appropriate paperwork with the editor in chief! In such cases, the result was two articles on the 'same' topic. (The 2/e Table of Contents was scoured multiple times looking for precisely these kinds of duplications but in the end, several proved elusive.)

In the large majority of cases, the content of the 'duplicate' articles was sufficiently distinct that both articles were retained, often with some retitling to help readers differentiate between them. For example, readers will find two articles on 'social identity.' One was recruited for the section on social psychology; the other for the sociology section. With rare exception, the two articles discuss different aspects of social identity from entirely different disciplinary angles; indeed, the two articles share only a small handful of common references. So it was an easy decision to retain them both: one appears here as Social Identity in Social Psychology; the other as Social Identity in Sociology. Careful readers will find perhaps a score of similar cases in the encyclopedia.

Alas, in a few regrettable cases, the overlap between duplicate articles was so pronounced that one of the articles had to be deleted. Since by the time these problems surfaced the articles had (often) been written and rewritten several times and had been accepted by both the section and area editors, the last-minute decision to delete a redundant article was painful. My sincere apologies to the authors involved.

Some redundancy in a work of this scope and aspiration is not only inevitable, it is probably also desirable. A reader interested in, say, social inequality will (one hopes) want to know what the sociologists, anthropologists, economists, and geographers all have to say about that topic. And if a few of the many articles on the topic say more or less the same thing, then what harm is done? Editors at all levels were asked to be alert to redundancies across articles and the editorial record shows that many were. That being said, quite a bit of topical redundancy no doubt remains, and that is not (in general) a matter of concern. It is what Smelser and Baltes refer to as the "inevitable residue of overlapping."

The Review Process

Once the table of contents had stabilized, each of the editors was asked to review the 1/e articles assigned to their section or area and come to various decisions. In some cases, 1/e articles could be reprinted more or less 'as is,' with perhaps some updating of references for readers seeking entry points into the current literature. This was especially the case with what were eventually designated as 'legacy articles,' e.g., Gabriel Almond's article on Civic Culture, James Gregor's article on Dictatorship, &c. In other cases, the 1/e articles needed some updating to be suitable for 2/e, either by their original authors when available or by others recruited specifically for the purpose. The general rule was that all 1/e authors would be offered the opportunity to do the updates themselves, and that other authors would be sought in the event of the original authors' declinations. In still other cases, the 1/e article was so obsolete than an entirely new article would be required. And then finally, the review of 1/e articles often revealed areas of current research that were inadequately covered; in these cases too, completely new articles would be sought.

Where appropriate, the relationship between the 1/e and 2/e versions of an article is spelled out in the article tagline. In many cases, there were issues of authorship to resolve — a 1/e article written by *X* and completely revised by *Y* is *Y*'s article although *X* might be identified in the tagline; but what of an article written by *X*, now deceased, and only modestly revised and updated by *Y*? Every decision rule that I formulated to resolve such issues soon confronted an exceptional case where the rule did not seem to apply. So in the end, the only workable rule was that everyone should get proper credit for their intellectual property, whether prime author or reviser, whether living or dead. If exceptions to this rule have crept into the final product (as they almost certainly have), I offer my apologies to those whose work has been slighted or improperly recognized. Deciding on proper authorship for many of our articles was a far more involved and difficult task than expected.

The section editors formed the first line of editorial defense and were the ones to whom article drafts were originally submitted. The section editors read and commented upon the draft articles and returned them to authors for revision. It is a rare article that appears here in its original form: on average, articles were revised two or three times before being sent to the area editors and subsequently on to me; in many cases, it was more like five or six revisions, with subsequent revisions at the request of the area editors and the editor in chief. And in some cases, articles were submitted to outside readers for independent review. As I stated earlier, the reviewing process was not blind, but it was quite thorough, as is reflected in the exceptional quality of the final product.

Internationalism and Inclusivity

A truly *International* Encyclopedia of the Social and Behavioral Sciences would of course require a global network of editors and authors *and* a commitment to internationalize the content of the work wherever possible. With respect to the editorial team for 2/e, this was definitely realized. The section editors and editors in chief who produced the first edition were drawn from only nine countries: The United States, Germany, Italy, Canada, Sweden, Australia, France, Switzerland, and the UK. Two-thirds of those editors were from the USA and only 13% were women. Area and section editors for 2/e represent 21 countries, US scholars make up only 38% of the total, and women comprise 36%. Thus, the proportional representation of women among the editors was nearly tripled in 2/e over 1/e while the predominance of the USA was halved. Nations represented among the editors of 2/e that were not represented in 1/e include Luxembourg, Greece, Finland, Japan, China, Ireland, Singapore, Spain, Russia, Austria, Israel, and the Netherlands. The presence of several Asian nations on this list is particularly gratifying. To be sure, the North Americans and Western Europeans still predominate, but they no longer monopolize the field.

Adding the International Board of Consulting Editors (see the following statement of Acknowledgments) increases the internationalism of the editorial team even further. Of the 45 members of that Board, only 12 (27%) are US social and behavioral scientists. Countries represented on that Board that are not otherwise part of the editorial team include three Central and South American nations (Venezuela, Argentina, Costa Rica), several Asian nations (the Philippines, Malaysia, South Korea, India), a few Western European nations (Norway, Denmark), two representatives from Central and Eastern Europe (Hungary, Croatia), two from the Middle East (Lebanon, Qatar), and one from South Africa. These editions bring to 35 the total number of countries with representation on the IESBS editorial team.

Much the same can be said of the 2/e authors, who are also more international than the 1/e authors had been. Smelser and Baltes noted in their Introduction that while authors from 51 nations were represented in the work,

58% of the authors were from North America and another 35% were from (mainly Western) Europe. "As to gender composition, 21% of the [1/e] authors were women." In 2/e, the proportion of women among the authors has increased slightly to approximately 25% and the percentage of North American authors has declined to fewer than half. Again, North America and Western Europe still contribute the larger share of the 2/e authors but the growing representation of social and behavioral science authors outside the West is both noteworthy and encouraging.

Another important point is that the international scope of the project is much more pronounced than editors' and authors' current affiliations would lead one to conclude. (This would have been equally true in 1/e as well.) Consider, for example, Michiru Nagatsu, author of our article 03053 on the history of behavioral economics. Dr Nagatsu was born in Japan and retains Japanese citizenship but was educated at Exeter and the London School of Economics and Political Science and wrote his IESBS 2/e article while on a postdoctoral fellowship in Finland. Or Guillermina Jasso, area editor for Area Three. Jasso was born in the USA, received her PhD from Johns Hopkins, and is on the faculty at New York University. By any standard, she would count as a US sociologist in our compilations. Yet her parents were Mexican of Basque, Spanish, Portuguese, and Dutch origins; Spanish is her native language; over the course of her distinguished career, she has published with coauthors from Germany, India, Israel, Mexico, the Netherlands, and Sweden; and she holds a permanent research fellowship at IZA, the Institute for the Study of Labor, in Bonn, Germany. Scoring her as 'USA' scarcely does justice to her biography or to the international perspective she brought to the editorial task.

What is true of author Nagatsu and editor Jasso is true in degrees of virtually the entire roster of IESBS participants. If one includes place of birth, citizenship, where educated, sites of research, visiting appointments, sites of fellowships, honorary professorships, invited lectures, and on through the list of highlights in a modern academic career, it is safe to say that every nook and cranny of the globe (save, possibly, Antarctica) is represented somewhere in the biographies of IESBS authors and editors. The true measure of internationalism, in short, is not so much where people come from or where they currently are, but rather the extent to which they bring a sensitivity and commitment to cultural and national differences into their work. Whether this was or was not realized in 2/e is for readers to decide.

Concluding Observations

Smelser and Baltes aspired in the first edition of this work to "assemble the whole range of knowledge – vast and complex as it is – of the social and behavioral sciences in one place." Since what does and does not qualify as 'social and behavioral science' is itself contested, it is not surprising that nearly every one of the market reviews commissioned by Elsevier to guide the development of the current edition noted content omissions in 1/e that reduced its usefulness and that needed to be addressed in a second edition. Critics can and no doubt will say the same about 2/e. I have already mentioned the nearly 800 articles that appeared on the 2/e Table of Contents at one time or another but that will not be found in the final product, either because agreeable authors could not be located or (less often) because agreeable authors never produced an acceptable article. And it is pretty easy to identify whole chunks of present-day social and behavioral science that are given short shrift, or no shrift at all, in this work – not because these chunks were judged to be unimportant but because limits of time, space, resources, and networks meant that some elements of the contemporary social science enterprise never came to our attention.

The social and behavioral sciences begin with what artificial intelligence guru Marvin Minsky once described as a "three pound computer made out of meat" – the human brain, which for all we know is the most complicated three-pound hunk of matter in the universe – and end with a thoroughly globalized culture and social structure that encompasses all aspects of our species' physical, biological, psychological, social, emotional, cultural, and spiritual lives. We are the most successful species ever to have inhabited the planet; we have colonized every inhabitable piece of dirt; our range extends everywhere; all the earth's resources lay at our command. To record all that has come to be known about human origins, evolution, language, culture, and social structure – everything we know about human emotions, identity, love, religion, family, economics, politics, domination, exploitation, and on through a very long list – would require orders of magnitude more volumes than the mere 26 volumes that comprise the present work.

We have come increasingly to the realization that what is social and human about our species is very intimately connected to our biological, genetic, and evolutionary inheritance. At the same time, the brain specifically and biological evolution more generally "cannot be viewed separately from the material, historical and

social circumstances that produce it" (Berntsen and Baker, 2015). As these authors put it, biology and culture are 'mutually constitutive.' Fifteen years ago, the editors of the first edition remarked on "ferment at the boundaries between the biological and the behavioral and social sciences." And while there are still important controversies, much of the ferment has yielded to cooperation as we are just now beginning to explore this endlessly complex web of interconnectedness between our biological and social selves. It is an easy and nearly inevitable conclusion, thus, that the third edition of the IESBS will contain a great deal more of the work being done at this intersection than 2/e was able to accommodate.

To conclude on a purely personal note, the 5 years I have spent working on this project produced many professional and personal gratifications, none quite so delicious as the certain knowledge that I would learn something new every single day. My work on 2/e exposed me to literature I never knew existed and to aspects of the social and behavioral sciences of which I was at best dimly aware. I can only hope that readers who come to these pages will find them as enriching as I have.

ACKNOWLEDGMENTS

A work of this scale is inevitably a communal enterprise involving many hundreds of editors, authors, reviewers, technical support people, colleagues, professional acquaintances, and friends who have provided input, advice, encouragement, and assistance over the past five years. Any listing is bound to be incomplete, so my apologies in advance to those who expected to be mentioned here but are not. Be assured that the slight is not intentional.

My negotiations with Elsevier about this project began early in 2010. By May of that year, I had committed to the project and have been working on it at varying levels of intensity ever since — often on weekends, during holidays, and whenever else I could snatch a useable chunk of time. So my first acknowledgment must be to my wife Chris for suffering through my five year obsession, always with understanding and affection, usually with good cheer. Chris is probably the only person in the world who is happier than I am that the project is now completed.

I must also acknowledge an enormous intellectual debt to the editors in chief of the first edition of the *International Encyclopedia of the Social and Behavioral Sciences*, Drs Neil Smelser and Paul Baltes (the latter now deceased). Dr Smelser was gracious enough to serve as Chair Emeritus of the project's International Board of Consulting Editors and to put himself at my disposal as, in his words, "a battle-scarred veteran." The basic intellectual structure of this work is adopted more or less wholesale from the Smelser—Baltes edition, with a few exceptions noted earlier in the *Introduction*. Without the original to serve as the starting point and blueprint, it is hard to imagine even embarking on such a task, much less bringing it to completion. Their edition was hailed as "the largest corpus of knowledge about the social and behavioral sciences in existence," which is to say that it formed an *extremely* solid foundation from which to build the work you now hold in your hands.

The first edition was organized into 39 sections overseen by a team of 53 section editors. The structure of the second edition is slightly different. It is divided up into 10 broad 'Areas,' each with an Area Editor overseeing the work of between four and eight Section Editors. In all, the second edition is thus comprised of the 10 Areas subdivided into 53 Sections; the 53 Sections were developed by a team of 76 Section Editors. So whereas Smelser and Baltes had 53 colleagues to help complete the work, I had 84 (two of the Area Editors also edited their own sections). On pages i-v in the front matter to this work one finds an Editorial Board list showing the Area Editors, Section Editors, Sections, names, and affiliations of the entire editorial team — a team whose dedication and effort in behalf of the project has vastly exceeded the rate of pay. A more helpful, productive, or delightful group of scholarly collaborators is difficult to imagine.

What readers see in the listed Editorial Structure of the work is the *final* editorial team as it existed when the work went into production. As would be expected in a project of this duration, there was considerable turnover within the team as the project developed and as death, competing demands, and general indifference all took their toll. I am grateful, nonetheless, to everyone who agreed, at least initially, to participate in the project, whether or not they were able to stay involved to the very end.

Susan Hanson (Geography) and Ulf Hannerz (Anthropology) are owed a special note of thanks because, of the 53 Section Editors involved in the first edition, these are the only two who agreed to reprise their roles in the second. (Both also wisely requested and received coeditors to carry part of the load.) Persuading people to serve who had no real idea what they were getting into was challenge enough, but these two suffered through 1/e and were willing to do it all over again for 2/e. And for that, I am especially grateful.

Many of the editors benefitted from the assistance of colleagues and graduate students at their various institutions. There was no mechanism built into the editorial process to keep systematic track of this

assistance and so the listing below is certain to be incomplete. But I can at least acknowledge those of whom I am aware who contributed time and intellectual energy to the effort: Liam Morton and Andrea Livingstone (Psychiatry); Jennifer O'Connor and Alana Dorris (Applied, Industrial and Organizational Psychology); Jen Hanis-Martin (Sexuality); David Budde, Annette Stimmer, Nikolas Ott, and Franziska Pfeifer (Institutions and Infrastructure of Social and Behavioral Sciences); Matthew LeDuc and Scott Freeman (Contemporary Cultural Concerns); and Simone Dudziak (Public Policy). To those named, my thanks. To those omitted, my apologies.

A special note of thanks to Dr Donald J. Barrett. Don was originally recruited to develop an entirely new section of the second edition on Gay, Lesbian, Bisexual, and Transsexual Studies, completed the section in short order, then e-mailed me to ask if there was anything further he could do to be helpful. Consequently, he took a major hand in developing the section on Biographies and was quite helpful with many other sections too. He appears in the Editorial Structure both as a Section Editor and as a Senior Editorial Associate to acknowledge his yeoman service to the entire enterprise. Also listed as a Senior Editorial Associate is my colleague Dr Amy M. Donley, who has been with the project since the very beginning and who, more than once, was all that stood between me and madness. I am proud to count them both as colleagues, collaborators, and friends.

I am also pleased to acknowledge Don Barrett, Andreas Hess, Harry Whitaker, John Berry, Barbara Miller, Scott Bentley, and Claire Byrne for their incisive and helpful commentary on previous drafts of the Acknowledgments and Editor's Introduction.

The project's International Board of Consulting Editors, chaired by Smelser and Dr Peter Marsden of Harvard University, was formed late in 2011 as a 'sounding board' to be used by the Area and Section Editors in searching for topics and authors and to help push for greater internationalism in our coverage. As it turned out, several members of this Board also stepped up to write entries in their areas of expertise. The composition of this Board and the affiliations of the consulting editors (as they were when the Board was first formed, not necessarily as they are today) are as follows: Neil J. Smelser, *University of California, USA*; Peter V. Marsden, *Harvard University, USA*; Ronald F. Abler, *International Geographical Union, USA*; John Bacon-Shone, *University of Hong Kong, China*; Roberto Briceño-León, *Universidad Central de Venezuela, Venezuela*; Roel Bosker, *Rijksuniversiteit Groningen, The Netherlands*; Michael Burawoy, *University of California, Berkeley, USA*; Nestor T. Searching for an editorial team to represent every social science discipline and every region of the globe quickly exposed the deficiencies in my personal network, so I am indebted to a very large number of scholars around the world for calling names of prospects to my attention, allowing me to drop their names in the recruitment effort, or otherwise helping me find people with the expertise and commitment required for the job. In most cases, this is a list of people who were invited onto the editorial team in some capacity,

demurred, but made valuable suggestions about others to contact. In several cases, people are listed because they engaged me in intellectual discussions about the structure, format, and even advisability of this work, or simply replied to a cold-call e-mail in pleasant, kind, helpful, or informative ways. Again ignoring the risk of omission, my sincere personal thanks to those named below for their contributions large and small to the final product:

Doug Anderton, Juri Allik, George Armelagos, Susan Ayers, Amanda Baumle, Janeen Baxter, Jess ben-Habib, Joao Biehl, David Blanchflower, Hans-Peter Blossfeld, Jason Boardman, Dorret Boomsma, Roel Bosker, Henry Brady, Martin Bulmer, Craig Calhoun, Miguel Centeno, William Cockerham, Mark Nathan Cohen, Amelie Constant, Simon Cottle, Connie Citro, Eileen Crimmons, James Curran, Scott Davies, Donatella Della Porta, George Downs, Francis Dodoo, David Dozois, Sonja Drobnick, Jaap Dronkers, John Dryzek, Riley Dunlap, Lauren Edelman, David Elesh, Paula England, Nancy Eisenberg, Geoffrey Evans, Miriam Faust, Robert Feenstra, Marcus Feldman, Stanley Feldman, Ronald Fischer, James Fowler, Jeremy Freese, Angela D. Weiss, Neil Whitehead, Pamela Wilcox, Bjorn Wittrock, Cornelia Woll, Gisele Yasmeen, and Barbie Zelizer.

Gratitude is owed as well to the many colleagues at Elsevier who contributed to the production of this volume. My first debt is to Claire Byrne, the project's Content Project Manager and the head of the Major Reference Works (MRW) team that managed the day-to-day *Sturm und Drang* of the project: aggrieved, confused, or delinquent authors, missed deadlines, testy and intransigent editors, and the often-maddening work style of the Editor in Chief. I am sure there were days when Claire wanted to tear her hair out, but to external appearances, she was an island of calm in a sea of turmoil. She was also exceptionally good at her job.

Claire's MRW team comprised Richard Berryman, Will Bowden-Green, Esmond Collins, Mark Harper, Sam Mahfoudh, Mike Nicholls, Gemma Tomalin, Joanne Williams, and Marise Willis. No matter what issue or problem I faced, one of these fine, capable people was always available to step up with a solution, invariably offered in a spirit of cooperation and good cheer. They have been to IESBS 2/e what tech support is to the modern computerized office. Getting this work completed without their help is inconceivable.

Thanks also to the succession of Elsevier's Acquisitions Editors who managed the finances and internal politics of the project: to Scott Bentley, whose gentle suasions pulled me into the project in the beginning; to Karen Maloney and Peter Labella who ran the show in the middle period; and to Lisa Tickner who was in charge at the very end. These are the people on the front line in the endless war between the publisher, who wants things done now and at minimal expense, and the Editor in Chief, who was always asking for more time and more money. The many dozens of amicable compromises necessary to bring the project to completion were all ably negotiated by Scott, Karen, Peter, and Lisa, and for that, I am grateful indeed.

The University of Central Florida and its Department of Sociology have provided a congenial home for the project. My thanks in particular to Dean Michael Johnson; to the current and former chairs of my department, Jana L. Jasinski and Libby Mustaine; to my faculty colleagues Liz Grauerholz, Phillip 'Hutch' Pollock, Bruce Wilson, Melanie Guldi, Stacy Barber, Tosha Dupras, and John Schultz; and to current and former graduate students Thomas Hall, Sara Strickhouser, Betsy Swart, Jordana Navarro, Marie Gualtieri, Shannon Simone, and Shannon Frey.

And most of all, my sincere thanks to the many thousands of authors whose work this is. When comparing the quality of the work contained within these pages to the authors' honoraria, it is obvious that IESBS 2/e is an act of collective charity by our authors to the disciplines they represent. It is my pleasure to thank our authors on behalf of the global social science community.

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the Encyclopedia is arranged as a series of articles in alphabetical order.

There are four features to help you easily find the topic you are interested in an alphabetical contents list, cross-references to other relevant articles within each article, subject classification index, and a full subject index.

1. Alphabetical Contents List

The alphabetical contents list, which appears at the front of each volume, lists the articles in the order that they appear in that volume of the Encyclopedia. It includes both the volume number and the page number of each article.

2. Cross-references

All of the articles in the Encyclopedia have been cross-referenced. The cross-references, which appear at the end of an article as a See also list, serve three different functions:

a. To draw the reader's attention to related materials in other articles.
b. To indicate material that broadens and extends the scope of the article.
c. To indicate material that covers a topic in more depth.

3. Subject Classification Index

This index appears in Volume 26 and groups articles under subject headings that reflect the broad themes of Social and Behavioral Sciences. This index is useful for making quick connections between articles and locating the relevant article for a topic that is covered in more than one article. Under some section headings, you will find subheadings, if it is appropriate for the articles in a subject area to be grouped into more specific subareas.

4. Contributors

At the start of each volume, there is list of the authors who contributed to that volume.

5. Index

The index appears in Volume 26. The index includes page numbers for quick reference to the information you are looking for. The index articles differentiate between references to whole article, a part of an article, and a table or figure.

Phantom Limbs

Abstract

The persisting sensory awareness of a limb after amputation has been termed the phantom limb. Phantom limbs are a normal and common sequela of amputation, occurring in approximately 90% of amputees. The phantom limb is a dynamic, frequently changing perceptual experience dependent upon ectopic activity from amputation stump neuromas, contributions from the sympathetic nervous system, alterations in the functional organization of sensory and motor nuclei after amputation, and the immediate emotional and psychological states of the individual. Phantom limb phenomena range from simple, diffuse sensations of tingling, to perceptually complex experiences of pains and lesions that originally were felt in the limb prior to amputation. While phantom pains and other sensations frequently are triggered by the perception of salient events, thoughts, and feelings, there is no evidence that the painful or painless phantom limb is a symptom of a psychological disorder. The sympathetic nervous system may provide an important link between higher brain centers involved in cognitive and affective processes and phantom limb sensations through its peripheral actions on primary afferent fibers located in stump neuromas by way of a sympathetic-efferent somatic-afferent coupling mechanism.

Many patients awake from the anesthetic after an amputation feeling certain that the operation has not been performed. They feel the lost limb so vividly that only when they reach out to touch it, or peer under the bedsheets to see it, do they realize it has been cut off. This startling realization does nothing to subdue the reality of the limb they experience, and may even intensify the sensations that define it. The first detailed description of this phenomenon was provided by the American Civil War surgeon, Silas Weir Mitchell (1871), who dubbed it the 'phantom limb.' The term so accurately captures the nature and subjective experience of the phenomenon that it has been adopted ever since. This article reviews the nature of phantom limb pain and nonpainful phantom limb sensations which arise after limb amputation.

Phantom Limb Pain

For many amputees, a distressing problem is phantom limb pain. While the distinction between a painful and nonpainful phantom is not always clear-cut, it is useful to separate them for purposes of description, classification, and treatment. Painful phantom experiences vary in a number of dimensions. These include intensity, quality, location, frequency, and duration. Many amputees report a painful intensification of the tingling, 'pins and needles' or paresthetic quality (i.e., dysesthesias) that defines the nonpainful phantom limb. Some sufferers describe bouts of paroxysmal shooting pain that travel up and down the limb. Others report the phantom to be in a cramped or otherwise unnatural posture that gives rise to excruciating pain. Many amputees describe the pain in the phantom limb as indistinguishable from the pain they experienced in the limb before amputation. In still others, the phantom may be immobile or paralyzed so that attempts to move it generate pain. Finally, the phantom is often the seat of an intense burning pain, as if the hand or foot were held too close to an open flame. Frequently amputees suffer from several types of pain. Phantom limb pain, it appears, is equally prevalent among men and women and is not related to side, level, age, or cause of amputation (Nikolajsen, 2013).

Surveys based on several thousand amputees reveal that between 78% and 85% of patients continue to experience significant amounts of phantom limb pain more than 25 years after amputation (Sherman et al., 1997). Prospective studies of the incidence of phantom limb pain are consistent with these estimates (Nikolajsen, 2013). Between 50% and 71% of amputees report phantom limb pain 2 years after amputation. There is a reduction in the frequency and duration of attacks over time. Equally striking is the low success rate of treatments for phantom limb pain: in the long term only 7% of patients are helped by the more than 50 types of therapy used to treat phantom limb pain (Sherman et al., 1997).

The different qualities of phantom limb pain, its high prevalence and incidence, and its low treatment success rate point to the complexity of the problem. Phantom limb pain is not a unitary syndrome, but a symptom class, with each class subserved by different etiologic mechanisms. There is not just one cause of phantom limb pain. The development and severity of this disorder are determined by the interaction of multiple factors that vary across individuals. These include ectopic activity from peripheral nerves that were transected during amputation and have formed a neuroma, contributions from the sympathetic nervous system, sensitization of central nervous system structures due to the effects of amputation, inflammation, and ectopic activity, alterations in the functional organization of sensory and motor nuclei, past experience with pain, and the immediate physiological, motivational, and psychological states of the individual.

Pain Memories in Phantom Limbs

A striking property of phantom limb pain is the presence of a pain that existed in a limb prior to its amputation (Katz and Melzack, 1990). This class of phantom limb pain is characterized by the persistence or recurrence of a previous pain, has the same qualities of sensation, and is experienced in the same region of the limb as the preamputation pain. Case studies of amputees have revealed pain 'memories' of painful diabetic foot ulcers, bedsores, gangrene, corns, blisters, ingrown toenails, cuts and deep tissue injuries, and damage to joints

and bony structures. In addition, the phantom limb may assume the same painful posture as that of the real limb prior to amputation, especially if the arm or leg has been immobilized for a prolonged period.

The proportion of amputees who report similar pain before and after amputation may be as high as 79% (Katz and Melzack, 1990), although according to prospective studies the incidence is approximately 10% at 1 year after amputation (Nikolajsen, 2013). Pain also persists in patients with deafferentation that does not involve amputation. Under these conditions, the involved body part is still present but it is devoid of sensibility due to an interruption in the supply of sensory (afferent) information (i.e., deafferentation). Brachial plexus avulsions, in which the sensory nerve roots supplying the arm and hand are torn from the spinal cord, often produce pain that is felt in the deafferented and anesthetic region. Similarly, patients with spinal cord injuries may complain of pain referred to body parts below the level of the transection, including, for example, a patient who continued to feel the pain of an ingrown toenail after a complete spinal cord break (Katz and Melzack, 2003).

Painful and nonpainful sensations also persist or recur after surgical removal or deafferentation of body structures other than the limbs, such as breasts, teeth, and internal and special sense organs. Ulcer pain has been reported to persist after subtotal gastrectomy with removal of the ulcer. Patients have reported labor pain and menstrual cramps after total hysterectomy, rectal pain and hemorrhoids after removal of the rectum and anus, the burning pain of cystitis after complete removal of the bladder, and the pain of a severely ulcerated cornea after enucleation of an eye.

As noted above, not all phantom limb memories are of painful experiences. Nonpainful preamputation sensations do recur, but they are not as common and tend to include the sensation of objects that were once worn on the limb. These superadded sensations vary in complexity from such simple somatosensory qualities as the sensation of bandages that once wrapped a wound, a plaster cast, finger rings, and wristwatches to the multimodal, perceptually integrated phenomenon of a phantom foot clad in a sock and a shoe of specific type and color (Katz and Melzack, 1990).

Taken together, these case reports and studies of amputees reveal that pain memories are not merely images or cognitive recollections; they are direct experiences of pain that resemble an earlier pain in location and quality. They are perceptually complex experiences that may even involve information from multiple sensory modalities including visual, olfactory, tactile, and motor components that had accompanied the original experience. The precise details of the experiences of pain involve localization, discrimination, affect, and evaluation – that is, all the dimensions of perceptual experience – and these properties are a function of integrated brain activity. It is likely that the outputs of sensitized spinal cells activate the neural structures in the brain that subserve memories of earlier events.

The Nonpainful Phantom Limb

The most salient property of the nonpainful phantom is the tingling, paresthetic quality, but sensations of temperature, posture, length, volume, positional orientation, and movement are also very common (Nikolajsen, 2013). The incidence of the nonpainful phantom is estimated to be between 80% and 100%. In fact, the presence of a nonpainful phantom is so common that it is considered a 'normal' sequela of amputation. It is standard practice to prepare the patient preoperatively for its subsequent occurrence.

The frequency with which a painless phantom occurs does not appear to be related to the extremity, side, level of amputation, age, gender, or reason for amputation (Nikolajsen, 2013). There is considerably more variability in the estimates of the duration of the nonpainful phantom. In some amputees, the phantom may disappear within days or weeks of the amputation. In others, it remains unchanged for up to 60 years.

Fading, Telescoping, and Shrinking

In approximately 30% of cases, the normal phantom undergoes a number of predictable changes within several years of amputation (Katz and Melzack, 2003). These include fading, telescoping, and shrinking. Immediately after amputation the phantom limb usually feels of normal length and size. Over time, the proximal portions begin to fade and soon disappear (**Figure 1**). At this point, the phantom limb consists of only the extremity and major joints. These are felt at a normal distance from the body. The intervening parts have disappeared so that the phantom hand or foot feels as if it were hanging, unattached, in empty space. In the case of an amputation performed at the shoulder, the phantom limb may consist of only the lower arm and hand, with a gap between the shoulder stump and the phantom elbow. In approximately one-third of amputees, a process of 'telescoping' begins. Among upper-extremity amputees, the phantom is perceived gradually to approach the stump so that the hand is located in phenomenal space on a level with the elbow of the other arm. As the process continues, the gap between the stump and phantom continues to close; the amputee may find that the hand is protruding from, or attached to, the end of the stump. Later, the phantom hand may retract into the stump so that only the tips of the fingers jut out. In some cases, eventually even these may disappear completely and permanently into the stump.

There are times when a completely telescoped phantom will temporarily lengthen so that the hand or foot is once again felt at a normal distance from the stump. Less commonly, the converse also occurs; a phantom that is already telescoped may temporarily retract completely into the stump, or one that is of normal or shortened length may become even shorter. The circumstances and stimuli that bring about these changes are extremely varied and range from peripheral stimulation of the stump and other regions of the body to more central influences.

The process of telescoping is sometimes accompanied by a marked shrinking of the phantom to the dimensions of a child's limb. This gradual diminution in perceived size or volume occurs in both upper- and lower-limb amputees. The extent of shrinking that occurs is variable. Adult amputees have reported the phantom to be the size of a doll's or baby's hand, a silver dollar, or even as small as a postage stamp (Katz and Melzack, 2003).

Figure 1 Illustrations of a patient who sustained a complete forequarter amputation of his right shoulder in a work accident and later developed phantom limb pain. The figurines depict the process of telescoping following a series of treatments with transcutaneous electrical nerve stimulation. Dots represent points where stimulation was applied. Arrows indicate the sites of referred phantom limb sensations. (a) The patient reported a phantom limb of normal length that consisted of only the lower arm and hand, with a gap between the shoulder stump and phantom elbow. During stimulation applied at a point above the clavicle, the patient reported that his phantom hand had begun to swell and become warm. (b) In response to stimulation applied at a point on his right ear, he remarked that his phantom arm had 'telescoped' into the stump so that the elbow protruded from the stump. (c) Later, stimulation of the same point resulted in a further retraction of the phantom, leaving only the wrist and hand attached to the stump. Source: Adapted from Katz, J., Melzack, R., 1987. Cortical Maps and Phantom Limbs

Factors governing the fading, telescoping, and shrinking of the phantom are not well understood. The gradual fading of the phantom is thought to represent a perceptual correlate of the reestablishment of inhibitory control over hyperactive or spontaneously active cells that subserve the phantom. The gradual telescoping and shrinking have been hypothesized to depend upon input from intact peripheral fibers located in the stump. These experiences appear to be perceptual markers of the short- and long-term reorganizational changes that occur after amputation in central nervous system structures including the somatosensory (Katz and Melzack, 2003; Merzenich et al., 1984). The perceived distance between the phantom and the stump may be a function of the distance separating their respective representations in the cortical map. Cortical restructuring is also evident in other parts of the brain, including the posterolateral thalamus, premotor cortex, and vestibular regions. These findings suggest that the activation of dynamic brain networks is essential for the development and maintenance of phantom limb pain (Moseley and Flor, 2012).

Psychophysical Correlates of Phantom Limb Sensations

Although a normal phantom occurs whenever nerve impulses from the periphery are blocked or otherwise removed, it is also true that direct stimulation of the amputation stump frequently exaggerates the tingling or paresthetic quality of sensation typical of the painless phantom limb. Careful questioning of amputees reveals that the nonpainful phantom limb is not perceived as a static phenomenon. The paresthetic quality of sensation, which defines the phantom limb percept, is in a constant state of flux, with changes occurring in intensity, body part, or both.

One mechanism that accounts for the paresthetic component of the phantom limb is a cycle of sympathetic-efferent somatic-afferent activity (Katz and Melzack, 2003). Changes in the intensity of phantom limb paresthesias reflect the joint activity of cholinergic (sudomotor) and noradrenergic (vasomotor) postganglionic sympathetic fibers on primary afferents located in the stump and stump neuromas. Release of acetylcholine and norepinephrine from postganglionic sympathetic fibers produces transient vasoconstriction and heightened skin conductance responses. In addition, neurotransmitter release onto apposing peripheral fibers trapped in stump neuromas increases primary afferent discharge. This information is transmitted rostrally, where it gives rise to referred phantom sensations upon reaching central structures subserving the amputated parts of the limb. The moment-to-moment fluctuations in the intensity of phantom limb paresthesias reported by many amputees may, in part, reflect a cycle of sympathetic-efferent somatic-afferent activity. Increases in the intensity of phantom limb paresthesias would follow bursts of sympathetic activity, and decreases would correspond to periods of relative sympathetic inactivity. If central sensitization has also developed, through prior injury, trauma during amputation, or

peripheral inflammation, or if the sympathetic–sensory coupling involves nociceptors, the sensation may be one of dysesthesia.

Psychological and Emotional Processes Influence the Phantom Limb

The idea that emotional and psychological processes can cause pain traditionally has been tied to the notion of psychopathology. However, it is becoming increasingly clear that under certain circumstances pain may be triggered by these processes in psychologically healthy individuals as well. The aggravation or alleviation of pain referred to phantom body parts may be mediated in part by psychological processes that alter anxiety levels. Phantom breast pain after mastectomy is provoked by emotional distress in 6% of women 3 weeks after surgery, and in 29% 1 year later. Of lower-extremity amputees, 50% report that attacks of phantom limb pain are triggered by emotional distress as long as 7 years after amputation. In addition, both pain catastrophizing and coping styles have been implicated as important moderators of, and possible risk factors for, phantom limb pain (Vase et al., 2011; Richardson et al., 2007).

Psychological or emotional processes can bring about transient but profound alterations in the quality and intensity of phantom limb sensations. These processes include concentration, distraction, relaxation, fright, forceful reminders of the events that led to amputation, and witnessing cruel and violent acts. One amputee, interviewed by the present writer, described his reaction to an accident involving his wife by reporting "goose bumps and cold shivering down the phantom [leg]. It went through me. Everything emotional will get you that." Another amputee stated, "It's like everything I feel goes there – the good and the bad" (Katz and Melzack, 2003).

A Centrally Triggered Sympathetic-Efferent Somatic-Afferent Coupling Mechanism

The model schematically represented in Figure 2 outlines a mechanism through which cognitive and affective processes associated with higher cortical and limbic centers may alter phantom limb sensations. The reciprocal connections between cortical, limbic, and lateral hypothalamic structures are well documented. The lateral hypothalamus is involved in the control and integration of neural activity associated with

Figure 2 Schematic diagram illustrating a mechanism of sympathetically generated phantom limb paresthesias. Spontaneous sympathetic activity or excitatory inputs descending from the cortex (e.g., due to the perception of a salient event, loud noise, thought, feeling, etc.) increase the discharge rate of preganglionic (pg) sympathetic neurons with cell bodies in the lateral horn (LH) of the spinal cord and terminals in the sympathetic ganglion (SG). These neurons excite postganglionic noradrenergic (NA) cutaneous vasoconstrictor (cvc) and cholinergic (ACh) sudomotor (sm) fibers that impinge on effector organs (vascular smooth muscle and sweat glands) in the stump and on sprouts from large-diameter primary afferent (pa) fibers that have been trapped in a neuroma. The release of ACh and NA on effector organs results in increased electrodermal activity (EDA) and decreased blood flow (BF) to the stump. Release of these chemicals in the neuroma activates primary afferents that project to spinal cord dorsal horn (DH) cells subserving the amputated parts of the limb. These neurons, in turn, feed back to the preganglionic sympathetic neurons and project rostrally where the impulses contribute to the perception of phantom limb paresthesias. If DH cells have been sensitized due to injury, or nociceptive primary afferents are activated, then the perception may be one of dysesthesias. Source: Reproduced from Katz, J., 1992. Psychophysical correlates of phantom limb experience. Journal of Neurology, Neurosurgery, and Psychiatry 55(9), 811–821.

affectively charged behavior and has direct projections to the lateral horn of the spinal cord. The intensity of phantom limb paresthesias and dysesthesias may thus be modulated by higher brain centers involved in cognitive and affective processes via a multisynaptic network of descending inputs, which impinges on preganglionic sympathetic neurons, producing diffuse peripheral autonomic discharge and activation of primary afferent fibers located in stump neuromas.

Treatment for Phantom Limb Pain

Over the years, many different treatments have been tried for phantom limb pain, including surgical, pharmacological, physical, and psychological approaches (Nikolajsen, 2013). Surgical treatments are typically performed on the stump to remove neuromas that contribute to the pain or are directed at more central structures but these too have met with limited success, largely because they produce further deafferentation that contributes to maladaptive reorganization of sensory and motor brain areas. Preemptive analgesic strategies target limb pain prior to amputation with the aim of preventing phantom limb pain (Katz, 1997; Katz et al., 2011) but the evidence for their success is equivocal (Katz and Seltzer, 2009). More recently, several alternative mind–body approaches have been developed to target phantom limb pain including mental imagery training and mirror visual feedback, but it is too early to know whether they will prove to be effective (Moseley and Flor, 2012). Overall, despite the many forms of available treatment, not one has been effective in a majority of cases and there are few, if any, that provide permanent relief. Most amputees continue to suffer the tragedy of phantom limb pain.

Summary and Conclusions

The phantom limb is not perceived as a static entity but as a frequently changing perceptual experience dependent upon the current sensory input, emotional state, and past experience of the individual amputee. Phantom limb phenomena range from simple, diffuse sensations of tingling to perceptually complex experiences of pains and lesions that originally were felt in the limb prior to amputation. While phantom pains and other sensations frequently are triggered by the perception of salient events, thoughts, and feelings, there is no evidence that the painful or painless phantom limb is a symptom of a psychological disorder. The sympathetic nervous system may provide an important link between higher brain centers involved in cognitive and affective processes and phantom limb sensations through its peripheral actions on primary afferents located in stump neuromas. Of the many forms of treatment for phantom limb pain, not one has been effective in a majority of cases and there are few, if any, that provide permanent relief.

Pharmaceutical Industry: Political Economies of Drugs and Knowledge

Abstract

The pharmaceutical industry has become one of the most important agents of social change and contributors to social structure in the developed world, as well as having significant effects in other parts of the world. As a result, the industry also has become a site of research by anthropologists, historians, sociologists, and other scholars in science and technology studies. This article focuses on how: the pharmaceutical industry has been a major force behind international intellectual property agreements, spends large sums on medical research and enrolls a great many subjects in its clinical trials, has a substantial impact on medical knowledge and opinion, and shapes people's perceptions of health and illness.

The Pharmaceutical Industry as a Key Social Actor

Global pharmaceutical sales increase by 5–7% annually, and are projected to total approximately US $1 trillion in 2014. In North America and Western Europe, physicians write more than a dozen prescriptions per capita per year. These include many prescriptions for drugs from which few people will benefit and for conditions they cannot feel, such as drugs to lower cholesterol and blood pressure or to increase bone mineral density. Moreover, increasing numbers of people take drugs for purposes not traditionally seen as medical: to improve their sex lives, reduce their weight, thicken their hair, sleep better, and feel less anxious. Certainly, drugs are a long-standing phenomenon, a form of easy hope in a glass bottle or plastic vial. But this hope's recent growth is extraordinary, expertly nurtured in governments, physicians, and consumers by the scientific marketers of the pharmaceutical industry.

The pharmaceutical industry has become one of the most important agents of social change and contributors to social structure in the developed world, as well as affecting other parts of the world. As a result, the industry also has become the site of significant research by anthropologists, historians, sociologists, and other scholars in science and technology studies. Though there are many other facets to the industry, this article focuses on a few important features: the industry has been a major force behind international intellectual property agreements, spends large sums on medical research and enrolls a great many subjects in its clinical trials, has a substantial impact on medical knowledge and opinion, and shapes people's perceptions of health and illness.

Regulation: From Influence to Partnerships

Even though it has reacted strongly against most governmental attempts at regulation, the pharmaceutical industry has influenced, adapted to, and profited from those regulations. As a result, the industry today is very much a creature of its regulation. The distinction between pharmaceuticals and their lower-status counterparts – such as patent medicines, herbal remedies, supplements, illegal drugs, and traditional medicines – depends on demarcations that require certain medicines to be scientifically tested for their safety and efficacy, approved for particular uses and then prescribed by licensed physicians or sold through licensed pharmacies (e.g., Rodwin, 2011). For the most part, those demarcations are made by government regulators such as the US Food and Drug Administration (FDA), the European Medicines Agency (EMA), or the Japanese Pharmaceutical and Medical Devices Agency (PMDA). The regulations established by the FDA in the 1960s, and widely emulated elsewhere, were sometimes fiercely opposed by the industry (Tobbell, 2012). Although regulation has increased the cost of new drugs, it also has tended to improve their image.

More recently, the industry has attempted to reduce its costs by standardizing requirements internationally; this allows companies to use the same research for their applications for a drug's approval in many jurisdictions. An agreement by the largest pharmaceutical companies and the United States, Europe, and Japan, the International Conference on Harmonization (ICH), established a standardized multiphased clinical research process. In so doing it helped to make the testing of drugs a global phenomenon, even though it has been tempered by local therapeutic cultures (Daemmrich, 2004). It has been argued that the agreement has tended to harmonize standards 'downward,' resulting in overall weaker carcinogenicity testing, weaker reporting of adverse events, and less long-term monitoring of adverse events (Abraham and Reed, 2001).

The ICH is one example of close cooperation between the pharmaceutical industry and drug regulators. However, regulators are usually receptive to pressures to balance interests in safety and effectiveness with the financial interests of a thriving industry that, it is argued, provides long-term health and economic benefits. Thus, the experts who evaluate drug applications are expected to be 'friendly' to the industry even as they apply strict standards, and the regulator as a whole is expected to support the industry even as it upholds laws (Abraham, 2008). Close cooperation is facilitated by the fact that pharmaceutical companies and their lobby groups tend to have coherent and consistent interests, and are sophisticated stakeholders. The cooperation is also facilitated by the increasing reliance of regulators on revenue from the companies themselves: the UK's Medicines and Healthcare Products Regulatory Agency receives 100% of its funding for evaluating new drug applications from the applicants; in the United States the figure is 50%, and the European Medicines Agency collects 70% of its total budget from fees paid by pharmaceutical companies

 http://dx.doi.org/10.1016/B978-0-08-097086-8.85054-0

(Abraham, 2008). National regulators have, provocatively, been characterized as umpires of intellectual property claims, rather than protectors of the public (Mirowski and Van Horne, 2005).

The pharmaceutical industry also affects other aspects of government. In the early 1980s, a group of companies successfully put intellectual property at the top of the US trade agenda and helped to design not only international agreements, but also a very successful strategy for convincing other countries to sign onto those agreements (e.g., Drahos, 1995). Prominent in that group of companies were representatives of the pharmaceutical industry: the Advisory Committee for Trade Negotiations, formed in 1981, was chaired by the CEO of Pfizer, Ed Pratt, and its 1986 successor, the Intellectual Property Committee, consisted of 13 large companies including Pfizer, Bristol-Myers, Johnson & Johnson, and Merck, making pharmaceuticals the largest of the industry sectors represented on the committee; the chemical, computer, automotive, aerospace, and communication industries also were represented. These committees designed a strategy that combined the building of coalitions with non-US companies, forceful bilateral pressure to link intellectual property and other trade, and finally multilateral agreements built on those bilateral pressures (Drahos, 1995). The result was the Agreement on Trade-Related Aspects of Intellectual Property Rights, which has formed the basis for new intellectual property laws in countries around the world.

Clinical Research: From Research and Development to Risk-Managed Production

The pharmaceutical industry sponsors a majority of the 40 000 new trials initiated each year (CenterWatch, 2009). Annually, between 3 and 6 million people are enrolled in industry-initiated clinical trials. The bulk of these trials are conducted by contract research organizations (CROs), companies that perform research and development for profit (Mirowski and Van Horne, 2005). As an indication of their rising importance, CRO revenues increased from US $1 billion in 1992 to an estimated $27 billion in 2010. CROs are involved in nearly 60% of all industry-sponsored studies, and 75% of outsourced R&D expenditures. The rest of the industry's outsourced R&D goes to academic medical centers. It should be noted that contracts with CROs and academic centers may not be comparable: CROs may be winning contracts for trials that otherwise would have been done directly by pharmaceutical companies, and the reasons for a company sponsoring an academic-run trial may have as much to do with establishing or maintaining relations with academic researchers as with other needs for trials.

Contact with subjects may occur at various sites, including academic medical centers that have an intellectual interest in the particular research or that use trial income to support themselves, clinics at which physicians supply small numbers of patients as a supplement to their regular practices, clinics that specialize in trials and earn substantial income from the procedures performed, specialized hospital units that run difficult inpatient trials, and sites that cut costs to a minimum and may house hundreds of subjects – referred to as 'floater sites' in part because the expected lifespan of a low-cost clinic is short, as it is likely to run into regulatory or political problems. Trial income is a factor in almost all of these kinds of clinics, as pharmaceutical companies pay substantial fees per patient and/or per procedure (Fisher, 2009).

Nearly 50% of all trial sites are in North America, and almost 20% are in Western Europe. Those figures correlate well with North America's and Western Europe's shares of the international pharmaceutical market, reflecting various historical and current relationships between trials and drug consumption. Yet the geographical distribution of trials is changing quickly. An increasing number of sites are in Asia, Africa, South America, and Eastern Europe; there are significant West-to-East and North-to-South shifts.

Pharmaceutical companies have better-developed networks of investigators and potential investigators in North America and Western Europe. Moreover, having sites in these places helps to maintain some North American and European investigators as allies and potential authors of papers stemming from clinical research. But the costs of trials – in fees to physicians and subjects, and the cost of medical procedures – are much lower in many other parts of the world, even parts that have sufficient medical infrastructure to serve as good locations for trials.

Recruitment is one driver of clinical trial costs. Many people in the United States and Western Europe are unwilling to participate in trials, and many are ineligible because they are already being treated. Wealthier countries are often 'treatment saturated,' and therefore are poor sources of the more straightforward or even ideal 'treatment naïve' test subjects abundant elsewhere. Moreover, companies are sophisticated about populations; one former chief executive of a CRO says: "Companies can now pick and choose populations … in order to get a most pronounced drug benefit signal as well as a 'no-harm' signal" (quoted in Petryna, 2009: p. 17). This strategy requires access to larger populations, and often populations in multiple countries. India, for example, is well positioned to provide subjects. India's *Economic Times* wrote in 2004: "The opportunities are huge, the multinationals are eager, and Indian companies are willing. We have the skills, we have the people …" (quoted in Shah, 2006: p. 17). And perhaps most obviously, the costs per patient are considerably lower in India than in North America or Western Europe.

Ethical variability is a further reason for the globalization of trials. Different standards apply even between established members of the European Union and newly admitted members in Eastern Europe. When participants in lower-income countries try to apply basic international ethical standards, variability in circumstances leads to substantial variability in application. Thus, there have been cases of enormous differences in protocols between higher- and lower-income countries, and a few extreme cases have sparked considerable debate (e.g., Petryna, 2009: pp. 38–40). CROs take advantage of ethical variability to lessen the cost and increase the efficiency of trials; they also compete with each other and perhaps with academic medical centers, creating downward pressure on the implementation of ethical standards. There may also be public relations and liability pressures to move trials away from North America and Western Europe. Deaths and other severe adverse events are more likely to attract unwanted media attention in

pharmaceutical companies' core markets than if they occur elsewhere. Legal liabilities also tend to be much higher in North America and Western Europe, and especially in the United States, than in the rest of the world.

Professional research subjects, people who earn at least a substantial portion of their income by signing up for Phase I (healthy subject) clinical trials, may see their participation as a kind of risky labor (Abadie, 2010; Sunder Rajan, 2007). From such a perspective, they are exploited for their 'surplus health' (Dumit, 2012), which can be transformed into pharmaceutical company profits. However, from the perspective of the companies, and given the systems built around them, subjects are simply inputs to production, most immediately the production of knowledge that will contribute to the success of the drugs. Subjects are a key, perhaps the key, resource that CROs and clinics can provide.

Clinical trial knowledge is a necessary input for the authorization to market new drugs. It is also a key resource for selling those drugs once on the market. Trials, therefore, are implemented in places and in ways that maximize value – in terms of keeping costs low, increasing the chances of positive results, and leveraging relationships and credibility of researchers.

Illness: From Medicalization to Pharmaceuticalization

Medicalization became a major issue in the 1960s, as critics railed against the authority of physicians and the medical profession as a whole to take control over intimate events and processes, often simply through classification. Criticism of medicalization was especially prominent in challenges to psychiatry by scholars such as Michel Foucault and Thomas Szasz. Their work was later picked up and applied in different realms, especially by feminist scholars. As a result, there have been challenges especially to mental health diagnostic categories ranging from schizophrenia to anxiety and depression, and challenges to the medicalization of ordinary life events and stages, such as childbirth and menopause.

The focus on professions has lost some of its traction, and physicians today appear to be only one set of actors in struggles for control over bodies, health, and illness. Much medicalization, then, looks as though it is merely grease for the wheels of 'pharmaceuticalization' (e.g., Williams et al., 2011). This claim is made even more plausible by the fact that some of the standard objects of critics' attention, such as anxiety, depression, and menopause, are closely associated with new classes of drugs. To increase their sales, pharmaceutical companies engage in 'selling sickness' or 'disease-mongering': expanding awareness of diseases for which their drugs can be prescribed, and increasing the likelihood that people will see themselves as having those diseases. Moreover, at least some pharmaceuticalization is independent of medicalization, when people use drugs as remedies for difficulties that they do not necessarily see in medical terms, such as excess weight, sleepiness, lack of focus, and shyness (Williams et al., 2011).

The category of depression is widely understood as having been affected by the availability of drugs. Before the 1980s, depression was a relatively uncommon diagnosis, and was generally associated with the elderly (Healy, 2004). Beginning with the arrival on the market of Eli Lilly's drug Prozac in 1987, however, ever-increasing numbers of people have been diagnosed with depression and are disabled by depression (Whitaker, 2010). Diagnostic criteria for depression have continually broadened, and thus estimates of the prevalence of depression have risen dramatically. It is now the 'common cold' of mental disorders.

Prozac was the first widely prescribed member of the Selective Serotonin Reuptake Inhibitor (SSRI) family of drugs, now often called simply 'antidepressants.' Companies selling SSRIs have marketed both the drug and the disease. They have invested heavily in research on depression and antidepressants. They have promoted a serotonin-deficiency theory of depression, for which there is little evidence (Whitaker, 2010). They have established close connections with psychiatrists and other physicians who write textbooks, articles, and clinical practice guidelines (Healy, 2004). Through such means and others, the companies appear to have successfully established the disease both medically and culturally, helping physicians see it often and helping patients interpret their feelings and experiences in terms of it – perhaps even shaping their identities around it. The World Health Organization predicts that within 20 years more people will be afflicted with depression than with any other health problem.

Depression may seem like a special case, because it is a mental illness and because the boundaries between the disorder and sadness are malleable. However, many examples of somatic or bodily illness have been shown to have been strongly affected by marketing efforts, including such common chronic diseases as hypertension, diabetes, high cholesterol, and osteoporosis (Greene, 2007; Moynihan and Cassels, 2005). To take one of these examples, when the pharmaceutical company then known as Merck Sharp & Dohme introduced its anti-hypertensive drug Diuril in 1957, high blood pressure was a sign associated with an underlying disease, but was not itself generally viewed as a problem to be controlled. Even the definition of high blood pressure was a difficult matter, since blood pressure had a Gaussian distribution, and any dividing line between high and normal seemed arbitrary. Diuril dramatically lowered blood pressure, apparently only in people with elevated levels, suggesting that it might address root causes of the problem. In conjunction with an unprecedentedly successful marketing campaign, its effects established hypertension as a disease in itself (Greene, 2007). The mildness of side effects of diuretic drugs made it straightforward for companies and their agents to argue for their use to treat ever-broader populations with ever-lower blood pressures. Recommendations followed suit, and blood pressures that were once judged as within a normal range became high. Thus, people came to understand themselves as hypertensive or as disposed to hypertension; in at least one population, hypertensive African-Americans, the condition has become linked to racial identity (Pollock, 2012). The pharmaceuticalization process has continued as new and different antihypertensive drugs have been found and marketed.

Chronic conditions such as hypertension neatly fit a new model of health and illness. Whereas people once generally considered themselves healthy unless they felt ill or had visible symptoms, some changes have resulted in a new model of health (Dumit, 2012). The past half-century has seen the rise of

risk factors: familiar ones like diet, age, and sleep patterns, and unseen and less familiar ones like cholesterol levels and high blood pressure. As a result, we are all at risk, differing only in our degrees of risk. Partly following from the rise of risk factors, we can be normal and unhealthy at the same time, at least when there is some hope for treatment. For example, the results of aging used to be simply unfortunate, but now we look for medical means to stave them off or treat them. There is no contradiction in the thought that people are unhealthy in one or another respect.

Marketing: Moving Medical Knowledge to Physicians and Consumers

Independent evaluations in France, the United States, and Canada indicate that only 10% of newly approved drugs offer significant advantages over existing treatments. Lack of innovation is all the more striking because the pharmaceutical industry portrays itself primarily as doing research and development, and only incidentally involved in marketing, advertising, and sales. This portrayal is necessary, since customers demand that drug decisions be based entirely on good evidence about health benefits and costs, and not on hearsay, fashion, or advertising.

Despite its apparent lack of innovation, the pharmaceutical industry consistently has the highest ratio of profit to investment among industries in the Fortune 500 companies. Paradoxically, then, innovation may not be required for high profits.

Pharmaceutical companies can attempt to structure and restructure medical knowledge in different ways, such as through innovative drug discovery or hegemony over medical knowledge and its communication. The latter, it appears, is a better investment of resources (Gagnon, 2009). Therefore, the industry has accumulated resources for shaping areas of medical knowledge, leading to greater profits than they could reap from investments in traditional drug research and development. Medicine's (and regulators') focus on expensive clinical trials in particular has meant that pharmaceutical companies are in a good position to control scientific knowledge about their products.

To physicians, some of the most visible conduits of both pharmaceutical marketing and communication are sales representatives, who can be important movers of medical knowledge. These 'detailers' beat paths from office to office, trying to earn a minute or so of a physician's time to make a sales pitch. In addition to bringing food for the staff and drug samples to be given away to patients, sales representatives bear reprints of the articles their companies have created to give scientific backing to their pitches. An article is a gift of knowledge, an apparent step away from the normal commercialism of the representatives. The knowledge not only buttresses sales jobs, but its status as a gift provokes a return, in the form of prescriptions (Oldani, 2004).

Sales representatives have limited status and influence, so the pharmaceutical industry often develops and turns to 'key opinion leaders,' typically referred to as 'KOLs,' to disseminate scientific information (Sismondo, 2013). The term 'key opinion leader' derives from research by the sociologist Paul Lazarsfeld and his students on structures of influence in such domains as politics, fashion, culture, and medicine. As the term itself suggests, pharmaceutical companies hire KOLs primarily to influence others, to lead opinions in the directions that the companies prefer. For this reason, relations between the companies and KOLs are ideally, from the point of view of the companies, part of general 'KOL management' plans.

There are different kinds of KOLs. At the low end of the totem pole are ordinary physicians – whether general practitioners or specialists – who are paid to speak to other physicians. They become part of the 'speakers bureaus' for particular drugs, and give talks in clinics over lunchtime to other physicians assembled by sales representatives around a buffet lunch. Or they might be after-dinner speakers at events for physicians, again organized by sales representatives. Higher up on the totem pole, and better paid, are researcher KOLs. These are people who have a significant research profile and whose value to pharmaceutical companies might stem from any number of activities. They might be paid to speak to other researchers, patient groups, or to physicians at continuing medical education sessions. They might be consulted on current medical, marketing, or research issues. They might serve as authors on medical journal articles stemming from company-led research. Or they might contribute to research either by recruiting patients for trials or by initiating their own trials.

One useful way in which researcher KOLs can help establish a pharmaceutical company's preferred knowledge base is by serving as (unpaid) authors on 'ghost managed' manuscripts – manuscripts that pharmaceutical companies control or shape, in ways opaque to readers, through multiple steps in the research, analysis, writing, and publication process (Sismondo, 2009). Although pharmaceutical companies have long used scientific data to convince physicians to prescribe their products, the rise of 'publication planning' over the past three decades has led companies to systematically treat data as an important resource to be managed and marshaled. When potentially major drugs come out, their manufacturers flood medical journals with articles about the disease and the drug.

This is a carefully orchestrated process. Companies propose and design multiple manuscripts around studies by lumping and splitting data. Hired medical writers produce first drafts and edit many papers, and medical education and communication companies expertly shepherd manuscripts through the publication pipeline – not only writing medical manuscripts, but communicating with the formal authors of those manuscripts, submitting them to medical journals where they should have impact, and tracking their progress and effects.

A considerable amount of the medical literature on newly patented drugs is ghost-managed. The CROs hired to run clinical trials have no interest in publishing the results under their own names – they produce data that are wholly owned by their sponsors. Thus, pharmaceutical companies have complete control over roughly half of all clinical trial data. More than 50 agencies advertise publication planning on the Internet. Some boast of having hundreds of employees and handling many hundreds of manuscripts per year. The industry is large enough that there are two competing international associations of

publication planners that organize meetings and seminars. One of those associations, the International Society of Medical Planning Professionals, has over 1000 members. Both ISMPP and its competing association, The International Publication Planning Association, hold annual conferences, and the latter hosts regional conferences. Planners handle dozens of manuscripts per year. From the few cases where there is hard data, it appears that roughly 40% of medical journal articles mentioning major new in-patent drugs are parts of individual publication plans on the drugs (Healy and Cattell, 2003; Ross et al., 2008). This level allows a company to attract interest in a drug and shape perceptions of it under the names of apparently independent authors.

Pharmaceutical companies also provide substantial amounts of funding for continuing medical education (CME) courses in the United States and in some other countries. In the United States, they are legally allowed to provide organization, pay for speakers, help speakers prepare their talks, and provide entertainment for participants. The companies do not control the content of accredited CMEs, but if they have chosen their speakers well, supported those speakers' research, and given speakers templates and slides for earlier talks, these courses will convey the companies' preferred messages.

On the whole, pharmaceutical companies are effective at marketing to physicians, whether via advertisements and sales representatives, or KOLs and other conduits for scientific literature. Marketing directly to consumers is a larger challenge and more complex, because only small portions of the general population are potential consumers for most drugs, and because consumers need prescriptions from physicians for many drugs. In the United States, the world's largest market for drugs, many forms of direct-to-consumer advertising (DTCA) are legal and are widespread. Most other jurisdictions allow only limited forms of DTCA, such as disease state awareness advertisements; these make consumers more aware of symptoms and ailments, and that awareness can lead to increased prescriptions and consumption.

Research, education, and marketing, then, are often fused. When a physician tries to learn about conditions and treatments, she typically turns to agents of pharmaceutical companies, whether they are the local sales reps or researchers and educators sponsored to spread particular messages. This allows the companies to sell without selling, a marketers' ideal.

Phenomenology in Sociology

Abstract

This article discusses the analytical approaches to the study of how cognitions and perceptions of social reality are reviewed under the rubric of phenomenological sociology. The roots of this stream of thought are traced through founders, modifiers, and adapters. Analytical and research techniques are presented along with discussions of a variety of applications to substantive areas of study. Recent trends, directions, and potentials in this field of inquiry are assessed.

Introduction

Phenomenology is a movement in philosophy that has been adapted by a number of sociologists and other scholars, and practitioners in the social and behavioral sciences to promote an understanding of the relationship between states of individual consciousness and social life. As an approach within sociology, phenomenology seeks to reveal how human awareness is associated with the production of social action, social situations, and social worlds (Natanson, 1970; Fergeson, 2006). In this presentation, the focus is on sociological phenomenology as an integrative approach linking subjective and objective processes that constitute the social world.

Phenomenology is practiced in sociology, psychology, national, regional and ethnic studies, anthropology, nursing, communications, education, history departments, etc. (Embree et al., 1996; Fergeson, 2006). Perhaps the most remarkable development in the field in the last decade has been the trend of sociological phenomenology to transcend disciplinary borders and expand outward into other related scholarly domains. Social phenomenology is a paradigm within many interacting schools of thought and research approaches evident in many aligned disciplines. A remaining task of sociological phenomenology is to clarify its relationship to philosophy and to other subject areas that apply a variety of strategies in using phenomenological elements (Bird, 2009). There does not yet seem to be a systematic effort to integrate and encompass cross-disciplinary phenomenological studies into a coherent body of investigation. However, phenomenology clearly provides underpinnings for constructionism, constructivism, postmodern and poststructuralist deconstructionism, ethnomethodology, everyday life analysis, conversation and discourse analysis, human sciences, communication studies, routine activities crime theory, and more.

Along with greater specificity and application of methods in focused research, phenomenological sociology is not as much of a debate issue as it had been in the 1970s and 1980s when the field was struggling for recognition. More currently, it is considered a relatively acceptable analytic modality moving away from the margins of scholarly inquiry into a more conventional if not quite a central role. Phenomenological approaches are applied in research methodologies such as ethnography, case study, intensive interviewing, observational study, counseling research, and other qualitative methods.

Background

Phenomenology was initially developed by Edmund Husserl (1859–1938), a German mathematician who posited that the objectivism of science precluded an adequate apprehension of the world (Husserl, 1931, 1970, 2012). He presented various philosophical conceptualizations and techniques designed to locate the sources or essences of reality in human consciousness. Alfred Schutz (1899–1959) brought Husserl's approach into sociology to provide a foundation for Max Weber's theory of action and eventually roused interest in other of the social–behavioral sciences (Schutz, 1967). Schutz distilled from Husserl's rather dense writings a socially relevant approach. Schutz described how subjective meanings give rise to an apparently objective social world (Heiskala, 2011; Schutz, 1962, 1964, 1966, 1970, 1996; Schutz and Luckmann, 1973; Wagner, 1983). Research in this vein has been rich and ongoing (Endress et al., 2011; Langan and Barber, 2011).

Schutz's migration to the United States prior to World War II, along with that of other phenomenologically inclined scholars, resulted in the transmission of this approach to American academic circles and ultimately to render it into its current diverse manifestations. Two fundamental expressions of this approach emerged in the 1960s frequently referred to as 'reality constructionism' and 'ethnomethodology.' Reality constructionism synthesized Schutz's distillation of phenomenology and the corpus of classical sociological thought to account for the possibility of social reality (Berger, 1963, 1967; Berger and Berger, 1972; Berger and Kellner, 1981; Berger and Luckmann, 1966; Potter, 1996; Gergen, 2009). Ethnomethodology integrates the Parsonian concern for social order into phenomenology and examines the means by which actors make ordinary life possible (Garfinkel, 1967; Garfinkel and Sacks, 1970; Francis and Hester, 2004; Pollner, 2012a,b). Reality constructionism and ethnomethodology are recognized to be among the more fertile orientations in the field of sociology (Ritzer, 2008; Nasu et al., 2012).

Additional sources and directions for phenomenological sociology are suggested by a review of Heidegger's approach (Aspers, 2010). Merleau-Ponty's phenomenology has led to a number of interesting studies including one that offers an interesting meditation on dance and digital technology as embodied intentionality (Kozel, 2008). There has been some recent interest in reviving the phenomenological work of

Scheler with his concept of developing 'spirit' as a unifying concept (2008). Lock and Strong (2001) suggest other sources for a diversification of phenomenological thinking in such philosophers as Gadamer (1876–1928), Ricoeur (1913–2005), and Levinas (1906–95).

Phenomenology is used in two basic ways in sociology: (1) to theorize about substantive sociological problems and (2) to enhance the adequacy of sociological research methods. Since phenomenology insists that society is a human construction, sociology itself, and its theories and methods are also examined as constructions (Cicourel, 1964, 1973; Ragin and Amoroso, 2010). Thus, phenomenology seeks to offer a corrective to the field's emphasis on positivist conceptualizations and research methods and measurement practices that may take for granted the very issues that phenomenologists find of interest. Phenomenology presents theoretical techniques and qualitative methods that both illuminate the human meanings of social life and the methods used to engage in sociological study.

Phenomenology has until recently been viewed as a challenger of the more conventional styles of positivistic sociological work and has played a role in emergence of postpositivist research modes. Increasingly, phenomenology is coming to be viewed as an adjunctive or by some as an integral part of the discipline, contributing useful analytical tools to balance objectivist approaches (Aho, 1998; Levesque-Lopman, 1988; Luckmann, 1978; Psathas, 1973; Rogers, 1983). Many research methods' texts in a variety of disciplines now provide extensive explorations of social phenomenological methods lending an increasing degree of scholarly legitimacy to interpretive analysis (Cresswell, 2012; Bernard, 2012).

Techniques

Phenomenological inquiry operates rather differently from conventional social science (Darroch and Silvers, 1982). Phenomenology is a philosophical orientation rather than a conventional theory. It does not generate deductions from propositions that can be empirically tested. It operates more on a metasocial plane, demonstrating its premises through descriptive analyses of the procedures of self, situational, and social constitution. Through its demonstrations, audiences apprehend the means by which phenomena, originating in human consciousness come to be experienced as features of an external world.

Current phenomenological techniques in sociology include the method of 'bracketing' (Bentz, 1995; Hurlburt, 2011; Ihde, 1977). This approach lifts an item under investigation from its meaningful context in the 'common-sense world,' with all judgments and presuppositions suspended. Rather, a reduction is performed in which the item is assessed in terms of how it operates in consciousness: What does the notion do for those who define themselves within its domain? A phenomenological reduction both plummets to the essentials of the notion and ascertains its meanings independent of all particular occasions of its use. The reduction of a bracketed phenomenon is thus a technique to gain new theoretical insight into the meaning and overt products of intentional projections from consciousness. A recent formulation of this technique focused on the bracketing of materiality, technology, and embodiment (Goeminne and Paredis, 2011). Leonardi (2008) explored the implications of deterministic conceptualizations or 'inevitability' on the implementation of new technologies to the benefit of particular actors within an organization.

Phenomenological tools include the use of interpretative, empathic, and introspective methods to offer a detailed description of the external consequences of intentional consciousness (Hitzler and Keller, 1989; Smith et al., 2009). Introspection requires the phenomenologist to use his or her own subjective process as a resource for study, and an empathic effort is needed to apprehend the mind of the other (Helle, 1991; Truzzi, 1974). Interpretation, introspection, and empathic tools of phenomenological analysis are considered to be procedures used both by ordinary individuals to carry out their projects and by researchers to penetrate to their meanings (Horgan, 2011). In this technique, the 'analytic' attitude is systematized as distinct from the 'natural' attitude of everyday life.

Since cognition is a crucial element of phenomenology, some theorists focus on social knowledge as the cornerstone of their technique (Berger and Luckmann, 1966). Frequently, religious thought is given primacy in the study of the sources and legitimations of mundane knowledge, and indirectly social construction (Berger, 1967). It is suggested that common-sense knowledge is produced, disseminated, and internalized. Subsequently, such knowledge is externalized from consciousness to be experienced ultimately as objectified phenomena. Thus, historically embedded meanings and discursive practices enable us to continually create and reinforce taken-for-granted knowledge or common sense. Common sense is then used as a means to pattern and institutionalize behaviors. From this angle, 'deconstructionism' may be viewed as a recursive analysis of this constructive process and we may be able to talk about a 'deconstructive phenomenology' (Watkin, 2009).

Recent work shows how phenomenological analysis extends cognition into the world (Rowlands, 2010). This approach tries to reject the concept of the mind as a purely internal process and seeks to locate the mind as a tied to externalities outside the body, and that mind and activity are reflexively integrated in constructive activity.

Phenomenological concerns are most frequently researched using qualitative methods (Bernard, 2012; Bogdan and Taylor, 1975; Cresswell, 2012; Denzin and Lincoln, 1994, 1998). Phenomenological researchers frequently undertake analyses of small groups, social situations, and organizations using face-to-face techniques of observation and intensive interviewing (Bruyn, 1966; Psathas and Ten Have, 1994; Seidman, 2005; Turner, 1974). Ethnographic research frequently utilizes phenomenological tools (Fielding, 1988). Intensive interviewing to uncover the subject's orientations or his or her 'life world' is also widely practiced (Costelloe, 1996; Englander, 2012; Grekova, 1996; Porter, 1995). Qualitative tools are used in phenomenological research either to yield insight into the microdynamics of particular spheres of human life for its own sake or to exhibit the constitutive activity of human consciousness (Langsdorf, 1995; Lapan et al., 2011).

Techniques particular to the ethnomethodological branch of phenomenology have been developed to reveal the practices

used by people to produce a sense of social order and thereby accomplish everyday life (Cuff, 1993; Eberle, 2010; Leiter, 1980; Mehan and Wood, 1975; Rouncefield and Tomie, 2011). At one time, 'breaching demonstrations' were widely conducted to reveal the essentiality of taken-for-granted routines and the means by which threats to these routines were managed. Since breaching these routines sometimes resulted in serious disruptions of relationships, this technique has been employed more recently only with great caution in research and instruction (Rafalovich, 2006). Frequently, social situations are video- and audiotaped to permit the painstaking demonstration of the actions by which participants produce themselves, their apparent interpretations of the meanings of acts, and to ascertain how they structure a situation (Blum-Kulka, 1994; Jordan and Henderson, 1995; Ten Have, 2004). Conversational analysis has been used widely to describe how people make sense of each other through talk and how they make sense of their talk through their common background knowledge (Psathas, 1994; Schegloff and Sacks, 1974; Silverman, 1998; Wardhaugh, 2009). The interrelations between mundane and abstract reasoning are also examined in great depth as researchers expose, for example, the socially constituted bases of scientific and mathematical practice in common-sense thinking (Dennis, 2004; Knorr-Cetina and Mulkay, 1983; Livingston, 1995; Lynch, 1993).

Theory

The central task in social phenomenology is to demonstrate the reciprocal interactions among the processes of human action, situational structuring, and reality construction. Rather than contending that any aspect is a causal factor, phenomenology views all dimensions as constitutive of all others. Phenomenologists use the term 'reflexivity' to characterize the way in which constituent dimensions serve as both foundation and consequence of all human projects. The task of phenomenology, then, is to make manifest the incessant tangle or reflexivity of action, situation, and reality in the various modes of being in the world (Phillipson, 1972).

Phenomenology commences with an analysis of the 'natural attitude.' This is understood as the way ordinary individuals participate in the world, taking its existence for granted, assuming its objectivity, and undertaking action projects as if they were predetermined. Language, culture, and common sense are experienced in the natural attitude as objective features of an external world that are learned by actors in the course of their lives.

Human beings are open to patterned social experience and strive toward meaningful involvement in a knowable world. They are characterized by a typifying mode of consciousness tending to classify sense data (Kim and Berard, 2009). In phenomenological terms humans experience the world in terms of 'typifications': Children are exposed to the common sounds and sights of their environments, including their own bodies, people, animals, vehicles, and so on. They come to apprehend the categorical identity and typified meanings of each in terms of conventional linguistic forms. In a similar manner, children learn the formulas for doing common activities. These practical means of doing are called 'recipes for action.' Typifications and recipes, once internalized, tend to settle beneath the level of full awareness, which become 'sedimented,' as do layers of rock. Thus, in the natural attitude, the foundations of actors' knowledge, and use of meanings and actions are obscured to the actors themselves.

Actors assume that knowledge is objective and all people reason in a like manner. Each actor assumes that every other actor knows what he or she knows of this world: All believe that they share and all know a common sense. However, each person's biography is unique, and each develops a relatively distinct 'stock' of typifications and recipes. Therefore, interpretations may diverge. Everyday social interaction is replete with ways in which actors create the feeling and belief that common sense is shared, that mutual understanding is occurring, and that everything is OK. Phenomenology emphasizes that humans live within an intersubjective world, yet they at best approximate shared realities. While a paramount reality is commonly experienced in this manner, particular realities or 'finite provinces of meaning' are also constructed and experienced by diverse cultural, social, or occupational groupings.

For phenomenology, all human consciousness is practical – it is always of something. Actors 'intend' projects into the world; they act in order to implement goals based on their typifications and recipes, their stock of knowledge at hand. Consciousness as an 'intentional' process is composed of thinking, perceiving, feeling, remembering, imagining, and anticipating directed toward the world. The objects of consciousness, these intentional acts, are the sources of all social realities that are, in turn, the materials of common sense.

Thus, typifications derived from common sense are internalized, becoming the tools that individual consciousness uses to constitute a 'life world,' the unified arena of human awareness and action. Common sense serves as an ever-present resource to assure actors that the reality that is projected from human subjectivity is an objective reality. Since all actors are involved in this intentional work, they sustain the collaborative effort to 'reify' their projections and thereby reinforce the very frameworks that provide the construction tools.

Social interaction is viewed phenomenologically as a process of reciprocal interpretive constructions of actors applying their stock of knowledge at hand to the occasion. Interactors orient themselves to others by taking into account typified meanings of actors in typified situations known to them through common sense. Action schemes are geared by each to the presumed projects of others. The conduct resulting from the intersection of intentional acts indicates to members of the collectivity that communication, coordination, or something of the like is occurring among them. For these members, conduct and utterances serve as 'indexical' expressions of the properties of the situation enabling each to proceed with the interaction while interpreting others, context, and self. Through the use of certain interpretive practices, members order the situation for themselves in sensical and coherent terms: In their talk they 'gloss' over apparent irrelevancies, fill in innumerable gaps, ignore inconsistencies, and assume a continuity of meaning, thereby formulating the occasion itself.

Ongoing social situations manifest patterned routine conduct that appears to positivist investigators to be normative or rule guided. Phenomenologically, rules are indexical

expressions of the interpretive processes applied by members in the course of their interactions. Rules are enacted in and through their applications. In order to play by the book, the interpreter endeavors to use the rule as an apparent guide. However, he or she must use all sorts of background expectancies to somehow manage the fit between the particular and the general under the contexted conditions of the interaction, and in so doing is acting creatively. Rules, policies, hierarchy, and organization are accomplished through the interpretive acts or negotiations of members in their concerted efforts to formulate a sense of operating in accord with a rational, accountable system. This work of 'doing' structure to the situation further sustains its common-sensical foundations as well as its apparent 'facticity.'

Phenomenologists analyze the ordering of social reality and how the usage of certain forms of knowledge contributes to that ordering. Typified action and interaction become routinely accomplished or 'habitualized' behavior. Through sedimentation in layered consciousness, human authorship of habitualized conduct is obscured and the product is experienced as an external entity, a 'thing.' As meaning-striving beings, humans create theoretical explanations and moral justifications in order to 'legitimate' or justify their habitualized conduct as something other or even more than human products. Some of the more abstract justifications become legitimations and are located in higher contexts of meaning such as religious or patriotic belief. Thus, the conduct becomes 'objectivated.' When internalized by succeeding generations, the conduct becomes fully institutionalized and exerts compelling constraints or normative pressure over individual volition. Periodically, the institutions might be threatened by dissent or aberrant conduct. The response might be then to sustain the institution by explaining the variance as an individual deviation requiring that the individual be 'repaired' through therapy, treatment, punishment, resocialization, or some combination of means primarily designed to restore the sense of institutional normalcy. Thus, straying individuals who cognitively, affectively, or behaviorally 'migrate' or stray from institutional alignment are corrected.

The reality that ordinary people inhabit is constituted by these legitimations of habitualized conduct. Ranging from common-sense typifications of ordinary language explanations to theological constructions to sophisticated philosophical, cosmological, and scientific conceptualizations, these reality justifications or legitimations contribute to the maintenance of the paramount reality of everyday life. Moreover, segmented modern life, with its proliferation of meaning-generating sectors, produces multiple realities, some in competition with each other for adherents. In the current marketplace of realities, individual reality consumers, to varying degrees, may select their meaning sectors or legitimations, as they select their occupation, spouse, lifestyle, and possibly, their religion (Berger, 1967).

Practice

Doing phenomenological sociology involves procedures that are distinct from positivist research. Phenomenological practice is increasingly evident in sociology and related disciplines as more subjectivist work is published. The phenomenological analysis of mass media culture content, for example, applies the elements of the approach to yield an understanding of the reflexive interplay of audience's life worlds and program material (Wilson, 1996; Groys, 2012). Thus, TV talk show discourses or celebrity profiling may be described as social texts that are refracted by programmers from common-sense identity constructs. The visual realization yields narrative images that audiences are seduced into processing using their own experiences. The viewers' life worlds and the TV representations are blended into reality proxies that provide viewers with schema to configure their personal orientations. Subsequently, programmers draw upon these orientations as additional identity materials for a new content development.

Phenomenological work with young children examined how both family interactions and the practices of everyday life are related to the construction of childhood (Davilla and Pearson, 1994). Penetrating the inner world of children requires that the phenomenological practitioners view the subjects in their own terms, from the level and viewpoints of children (Waksler, 1991; Shehan, 1999). Such investigation shuns adult authoritative and particularly scientific perspectives and seeks to give voice to the children's experience of their own worlds. Infants' and children's communicative and interactive competencies are respected and are not diminished by their movement toward higher level functioning (Sheets-Johnstone, 1996).

At the other end of the lifecycle, phenomenologists investigate how aging and its associated challenges are constituted in the consciousness of members and helpers (Starr, 1982). The struggle for meaning, memory, and identity during aging accompanied by deteriorative changes may be facilitated by the availability of constructs that permit the smoother processing of declining capabilities (Li and Orleans, 2002). Members of cultures that stock typifications and recipes for managing aging and pain effectively may well be more likely than others to construct beneficial interpretations in the face of the challenges posed by aging (Encandela, 1997). Phenomenological work encourages the helpers of the elderly to gain empathic appreciation of their clients' life worlds and to enhance the quality of their care through the use of biographical narratives that highlight the individuality and humanity of aging persons (Heliker, 1997). Caregivers for the elderly who were able to adequately manage their feelings of powerlessness and incompetence in relation to their work ideals could be more effective (Juthberg and Sundin, 2010).

The healing professions, particularly nursing, seem to be deeply imbued with a phenomenological focus on the provision of care based on a rigorous emphasis on the patient's subjective experience (Benner, 1995; Edwards, 2003). Substantial attention has been devoted to the ethical implications of various disease definitions, to how language shapes the response to illness, and to how disease definitions and paradigmatic models impact communication between health professionals and patients (Rosenberg and Golden, 1992). Recent applications of social phenomenology in relation to nursing analyzed the construction of bioethical concerns (Shaw, 2010), and the health care consultation process was dissected using video to develop a schema to enhance the quality of communication (Bickerton et al., 2010).

Significant work on the phenomenology of disability has demonstrated how the lived body is experienced in an altered form and how taken-for-granted routines are disrupted invoking new action recipes (Toombs, 1995). Interpretive research with autistic young people has been successfully conducted (Huws, 2008). Nonconventional healing practices have also been examined revealing how embodiment and the actor's subjective orientation reflexively interrelate with cultural imagery and discourse to transfigure the self (Csordas, 1997). Further, phenomenological work has suggested that emotions are best analyzed as interpreted processes both embodied and embedded within experiential contexts (Blum, 1996; Solomon, 1997).

Studies of everyday life activities from a phenomenological foundation are abundant and robust in sociology (Pink, 2012). A number of introductory textbooks focusing on ordinary life have been published for decades with regular new editions (Henslin, 2012; Newman, 2011). Scott's (2009) text introduces students to the social phenomenology of everyday life. Scholarly journals, many of which are included in the references below, such as *Qualitative Research*, *Human Studies*, and *The Journal of Contemporary Ethnography* regularly include articles on the commonplace as constructive human endeavors.

Conclusions

For phenomenology, society, social reality, social order, institutions, organizations, situations, interactions, and individual actions are constructions that appear as suprahuman entities. What does this suggest regarding humanity and sociology? Phenomenology advances the notion that humans are creative agents in the construction of social worlds (Ainlay, 1986). It is from their consciousness that all being emerges.

Sociological phenomenology of the latter part of the twentieth century laid out the philosophical foundations of a program of theorizing and research that has been substantively addressed in the early part of the twenty-first century. Numerous studies employing phenomenological tools have demonstrated the utility of the approach and the steady progress of the field suggests that much more is to come. While remaining a lesser trend within the predominantly objectivist quantitatively oriented discipline of sociology, it has gained more than a measure of legitimacy and acceptance by the broader community of scholars.

While there are not many departments of sociology where phenomenological approaches are predominant, especially in the United States, many if not most departments do include at least one or a few phenomenologically inclined scholars. Some Canadian, European, and some non-Western universities in Asia and Latin America may even include a substantial number of phenomenologists. If further study is desired, readers are advised to review the authors referred to in this paper to consider the range of affiliations and the types of programs offered at various universities.

The future impact of phenomenology is reflected in its resonance with the interests and orientations of a substantial group of sociologists and practitioners in related disciplines. The goal of deriving a penetrating and productive insight into the practical consequences of consciousness with the precision and sensitivity of demanding scholarship is progressing well. The applications of phenomenology to diverse areas, only some of which are identified in this paper, hold great promise of substantial contribution to human understanding.

Among the frontiers of phenomenological analysis that could be more fully examined remain studies of the experiences of virtuality, cyberspace, and computer simulacra, the roots of scientific and technological formulations in everyday meanings and practices, media imagery in relation to explanations of unusual events, representations of celebrities and identity formation, ethnic and racial identity constructions, diverse family patterning, educational assessment practices, crime meanings, and of other as yet unmentioned domains of knowledge.

Due to its lack of presumption, emphasis on subjectivity, its flexible applicability, and its many streams of phenomenological inspiration, this approach has proven beneficial in the opening years of the twenty-first century, and it is likely to continue developing by specialization and focus as we move deeper into the new millennium.

Abstract

Even though phenomenology had a single founder, Edmund Husserl, it has developed into a diverse tradition that warrants speaking of phenomenologies in the plural. Transforming the objects and actions of everyday experience into phenomena, it aims at clarifying the ways of givenness of the world in relation to an experiencing subject. From the very beginning, sociality has been among its areas of research, ranging from the question of other minds and emotions and of embodiment as the basic human condition, to an investigation of the lifeworld as the ground and horizon of all experience and the other as a fundamental challenge to the autonomous subject. In this way, it has inspired research in various other disciplines including cognitive science.

Phenomenology and Phenomenologies

Phenomenology was one of the most influential philosophical traditions of the twentieth century and continues to influence philosophical thought and various other fields (sociology, political theory, art studies, theory of architecture, pedagogy, among others) today. While its roots lie in the same contexts and discussions in philosophy, logic, and psychology in the nineteenth century that were the foundations of analytic philosophy, this tie was severed long ago. Only recently the debate in the cognitive sciences has revitalized phenomenology in an area that had long been dominated by analytic approaches, promising a new dialogue between the two. Besides this, there have been various parallels to and convergences with developments in the pragmatist tradition.

Unlike many other philosophical traditions, phenomenology can be said to have a single founder: Edmund Husserl. Husserl (1859–1938) studied philosophy, mathematics, and psychology and devoted his first books to the theory of mathematics. In these books, he defended a theory that he was to oppose vehemently in later years, namely a psychologistic explanation of mathematics and logic. The publication of his *Logical Investigations* 1900–1901 amounted to a complete reversion of this earlier position, and it marks the beginning of phenomenology in the modern sense, which has little in common with earlier uses of the word (e.g., in Hegel's *Phenomenology of Spirit*). Husserl's basic insight was inspired by one of his philosophical teachers, Franz von Brentano: the fact of intentionality. Consciousness is always consciousness of something, just as symbolic reference is reference to something. Any investigation of the objects of consciousness has to be complemented by an investigation of the consciousness of objects and vice versa. In this relation, the objects are not constructed by consciousness but rather intuited as independent, and the task of phenomenology is to investigate these objects – among them logical and mathematical sentences – in the way they are given as phenomena (Husserl, 1901: pt. V).

Since the publication of the *Logical Investigations*, phenomenology has undergone several fundamental transformations, and as early as 1953 Paul Ricoeur called its history a history of heresies (Ricœur, 1953: p. 836). Considering this, it might be more appropriate to speak of phenomenologies in the plural. The first of these heretics, however, was Husserl himself, whose transcendental turn in 1913 many of his earlier followers and collaborators (Adolph Reinach, Moritz Geiger, Max Scheler, among others) were not willing to go along with. The 'realist phenomenology' they adhered to did not consider the meticulous analysis of the a priori structures of consciousness Husserl undertook in the first volume of his *Ideas Pertaining to a Pure Phenomenology and Phenomenological Philosophy* (Husserl, 1913) to be warranted or necessary. Instead, they devoted their attention to social and legal phenomena, art, literature, and a variety of other topics that appeared in Husserl's own writings only much later. The major figure after Husserl who even tended to outshine his former teacher appeared on the scene in the 1920s: Martin Heidegger. His existential and ontological transformation of phenomenology paved the ground for subsequent modifications that are associated with names like Jean-Paul Sartre and Maurice Merleau-Ponty who stressed the role of the body and brought into play political topics. Phenomenological heritage can even be detected in those French philosophers whose background lay in phenomenology but who decided to distance themselves from it, including Jacques Derrida, Jean-François Lyotard and others.

In his *Ideas*, Husserl introduced a basic methodical tool he called 'phenomenological' or 'transcendental reduction,' meaning a fundamental change of attitude toward the world (Husserl, 1913: sections 31–32). Without giving up his worldly activities, the researcher was supposed to turn himself into an observer who withdrew from all involvement, methodically transforming things and actions into phenomena and thereby making them accessible in the way they show themselves – a shift from the 'what' to the 'how' of the world, as it were. Even though later theoreticians have expressed doubts about the feasibility of this operation, the necessity of some kind of break between the everyday attitude toward the world and its phenomenological treatment is generally accepted.

Husserl's early writings were primarily concerned with consciousness in a singular sense but the subject of intersubjectivity and social relations figured in his manuscripts and lectures from very early on. The concept of lifeworld that he

introduced in his later texts proved to be a fruitful starting point for sociological analyses. More fundamental, the question of how we can know or have access to others' minds and emotions has been an important phenomenological topic, and phenomenology's contributions to these questions have recently been adopted and developed in cognitive science. In phenomenological theory, the topics of other minds, the body, the lifeworld, and the other are all intertwined.

Minds and Emotions

In the beginning of the twentieth century, Theodor Lipps developed a concept of empathy ('Einfühlung,' literally 'feeling into') to explain not only our knowledge of other persons but also our understanding of art (Lipps, 1903: pp. 107–141). He posited the coupled natural drives of imitation and expression leading to a tendency to imitate perceived expressive movements, thereby reliving the content of their expression and finally 'feeling' this content 'into' the perceived body or work of art. To Lipps this was not an act but an unconscious instinct functioning automatically. Husserl and other phenomenological writers such as Edith Stein (Stein, 1917) drew upon this concept, modifying and criticizing it. According to Husserl's *Cartesian Meditations* (Husserl, 1931: sections 49–62), I perceive others' bodies and their gestures not as symbols but as immediate expressions of an inner life that is 'appresented,' i.e., given along with the visibility of their bodies without ever being truly present to me. Still there is an act of analogy or 'pairing' at the bottom of this which is not based on an actual comparison and judgment of similarity but still makes me the model and 'norm' of the others and lets them appear secondary to and dependent on the sphere of my own self. On the other hand, the objectivity of the world and its objects is based on their being objects not just for myself but for everyone. Even though this reconstruction was meant to counter the alleged solipsistic tendencies of transcendental phenomenology, the problems of reaching an intersubjective and cultural world from a transcendental subjectivity conceptualized as 'monadic' become very apparent.

Before Husserl, Max Scheler had proposed a theory that avoided any reference to 'Einfühlung,' instead relying on the observation of an immediate 'Nachfühlen' – correctly but misleadingly translated as 'empathy' as well – which formed the basis of any act of actual sympathy ('Mitfühlen'), i.e., compassion as an act of not only perceiving the other's sadness and remaining neutral toward it but sympathizing with other (Scheler, 1923: Chapter A 2). He sharply distinguished empathy and sympathy from mere contagion ('Ansteckung') where a person is affected by another's yawn or an infant by another's cries, and which contains no real reference to the other's feelings at all but comes close to a causal reaction. In neither case, however, do we first perceive a physical body which is then provided with an inner life, be it felt into, projected by analogy or inferred by an act of interpretation. To Scheler, this description was a fiction produced by scientific psychology.

As for Lipps and Husserl, emotions are referred to as the most salient instances of human expression while the argument is directed toward the more general question of how we perceive others as agents with an emotional and mental life. Scheler's basic point, which was later taken up by Merleau-Ponty and others and was endorsed by Wittgenstein (1967: sections 220, 225) is that there is no ontological gap between the visible body and the 'inner' life of a person, in a way that Cartesian theory would define it. Even though we do not actually feel the others' emotions, we do not infer them from outward signs or reconstruct them within ourselves either – rather, we see them *in* their behavior. We neither see an animated physical object nor an animated body but a person that exhibits sensible behavior. Theories that posit some kind of act of inference or analogy have difficulties explaining how these mechanisms can be at work even in early infancy where conscious acts of making inferences seem very unlikely.

Recently, this phenomenological position has been revitalized in the discussion on the theory of mind that has involved developmental psychology, philosophy, and cognitive science (Carruthers and Smith, 1996; Davies and Stone, 1995). The two most important theoretical approaches in this debate have been labeled 'theory theory' and 'simulation theory,' the latter of which bears some resemblance to the old theory of 'Einfühlung.' It proposes that we reconstruct others' mental and emotional states by simulating them within our own minds, performing an imaginary representation of what it would be like to be in their position (Gordon, 1986). Recently, the research on mirror neurons has been cited to support this view, providing it with a neuronal basis (Gallese and Goldman, 1998). The 'theory theory,' on the other hand, defends the view that we construct theories or folk psychologies concerning the inner life of others, inferring their beliefs, thoughts, and emotions on the basis of these theories. The strongest and most widely held claim by proponents of both theories is that simulation or theory are our primary means of accessing the mental state of others and that they are acquired early in childhood (Gopnik and Meltzoff, 1997) or are even innate (Baron-Cohen, 1995).

Both these theories have been criticized from a phenomenological point of view, aiming at their very premises (Gallagher, 2005: Chapter 9). The basic assumptions of the whole debate are Cartesian, conceptualizing the mind as a closed entity distinct from the body, and its focus has been explanation and prediction as primary goals of understanding others. All of these presuppositions can be contested on the grounds that they fundamentally misconstrue our basic stance toward the world which is characterized by pragmatic bodily interaction. Hence Shaun Gallagher proposes a third reconstruction which he calls 'interaction theory' (Gallagher, 2005: p. 208). In everyday interaction, our aim is not to theorize about the mind of others or to simulate its content but to make sense of what they do in a particular situation, being part of that situation ourselves, in order to respond to it and enter into interaction and/or communication. There is a primary intersubjectivity of bodily interaction that is accessible even to very young infants who show a pragmatic understanding of the motives and beliefs of others as they are manifested in their actions. This understanding precedes the explicit and rather detached reconstructions that are tested in the classical false belief experiments. Of course this does not mean that we never resort to theory or simulation at all but rather that these modes of reconstruction are not what our interaction with others as persons are based on. What

becomes obvious, however, is the basic role of our bodies in our interaction with and understanding of the world and other human beings.

The Body

In the posthumously published second part of his *Ideas*, Husserl granted the body a much more important position than he had in his previous writings (Husserl, 1952: sections 18, 35–42). He drew on the difference of 'Leib' and 'Körper' that is made in the German language, distinguishing 'Körper' as a physical entity considered from a detached point of view from 'Leib' (usually translated as 'lived body') as the primary way our own body and the bodies of others are given to us experientially. The lived body is that by means of which we experience the world and thus can never be completely objectified, and even though the bodies of others offer the possibility of objectification, we primarily experience them as experiencing the world as well. This entails a shift in the conception of consciousness: the lived body is not an object of consciousness but part of it, as it were. It is our primary mode of dealing with the world. The operation of withdrawal into a region of pure consciousness that characterized transcendental phenomenology thus becomes increasingly implausible. There is a continuity between mind and the lived body rather than an ontological gap, and the distinction between the lived body and the physical body, 'Leib' and 'Körper,' does not distinguish ontologically distinct entities but rather different perspectives on the same thing.

A similar position in a somewhat different theoretical context can be found in the work of Helmuth Plessner who studied medicine and zoology as well as philosophy with Husserl. Plessner's aim was anthropological but he argued from a phenomenological background (Plessner, 1928). On his view, humans are characterized by a dual way of relating to themselves and to the world, which he called eccentric positionality. They relate to the world from a centered position analogous to that of an animal, but they also relate to this relationship from a position that is not centered but situates itself on the border of self and world. This entails a dual relationship to one's body: we *are* a 'Leib' and *have* a 'Körper.' According to this theory, consciousness and reflexivity are firmly rooted in biology.

It was Merleau-Ponty who drew the consequences of these positions within phenomenology. Drawing on contemporary psychology, psychopathology and neuroscience, as well as on Husserlian phenomenology, he outlined a theory of the lived body as a relation to the world, an 'être-au-monde,' which is usually translated with Heidegger's term 'being-in-the-world' but could also be rendered as 'being-towards-the-world' (Merleau-Ponty, 1945). According to him, it's not the Cartesian 'I think' but the Husserlian 'I can' (move, perceive, act, etc.) that must be placed at the center of subjectivity, and the subject must be conceived as an embodied agent.

While Husserl kept his distance toward science in general and contemporary psychology in particular, Merleau-Ponty was an avid reader of psychological, neurological, biological, and later linguistic research, trying to integrate it into a philosophical account of perception. Gestalt psychology and neurology provided him with the insight that the functions of the body cannot be viewed in isolation and have to be understood within the context of its perceiving and acting in the world. From this it follows that an adequate theory of perception must also be a theory of the lived body and vice versa. As a consequence, Merleau-Ponty conceived of mind neither as an entity in itself nor as a mere function of neuronal structures and operations, but rather as the situated activity of bodily beings in interaction with each other and the world. This position is as far from Cartesian dualism as it is from a simple monism. There is a relative independence of higher processes of mind that cannot be reduced to functions of the lived body nor completely severed from it.

Many of the research perspectives Merleau-Ponty relied on and developed were discontinued in the years after the *Phenomenology of Perception* was published, and in the new cognitive science the computational model of the mind was virtually undisputed. Only recently has cognitive science turned toward an account of cognition that has been labeled as 'enactive' or 'embodied,' returning to some of Merleau-Ponty's central theses. In what has been called the 'third wave' in the development of cognitive science, the role of body in cognition is increasingly being acknowledged (Varela et al., 1992; Noe, 2004). From the side of phenomenological philosophy, there have been attempts to follow Merleau-Ponty in critically interpreting the findings of cognitive science and fitting them into a phenomenological framework which in turn has to be modified (Gallagher, 2005; Gallagher and Schmicking, 2010). The question of naturalization is being debated once again but its premises have changed. Various proposals have been made about how phenomenology and neuroscience can mutually inform each other, dropping the idea of a complete convergence (Petitot et al., 2000; Gallagher, 2012: Chapter 1).

The Lifeworld

Husserl first used the term 'Lebenswelt' in a manuscript in 1917 but the topic of the everyday world of the 'natural attitude' was present long before that. Not until 1935, however, did the lifeworld figure in his published writings. Before that, important contributions to a theory of the lifeworld were made by two of his followers, Martin Heidegger and Alfred Schütz. In *Being and Time*, Heidegger introduced the concept of 'Zeug' ('equipment') to describe the primary givenness of things in the everyday world (Heidegger, 1927: sections 14–18). According to Heidegger, our world is not populated by objects of contemplation but by things of practice that form a web or nexus of tools and equipment ('Zeugzusammenhang') where every one thing refers to others and to the practical context it belongs to and can be used in. Consequently, it is not theoretical cognition that marks our primary approach to the world but a practical kind of knowledge of handling things. Primarily the world is that which we find ourselves in, in the horizon of which we act, not a collection of objects; space is characterized by proximity and remoteness, not by a neutral measuring of distance. When he calls the 'Dasein' (i.e., human beings) 'being-in-the-world,' this is not to be understood as the presence of a physical entity within a container-like world but a type of being involved, of handling things, a presence to the world. According to Heidegger, this is

what ontology must take as its starting point, not a neutralized theoretical view.

Husserl's own point of departure in the *Crisis of European Sciences* was similar but somewhat more urgent: he diagnosed a fatal disappearance of the problems of humanity within the prevailing scientific ontology, resulting in the danger of radical skepticism and nihilism, and proceeded to work out a genealogy of natural science from the lifeworld (Husserl, 1954). He did not consider the series of subsequent abstractions in itself to be problematic, but the fact that this genealogy tended to be forgotten and its endpoint taken as a truer reality. A phenomenological 'science' of the lifeworld was supposed to counter these tendencies and ground our self-conception in a deeper understanding of our primary reality. The lifeworld as he described it is a sphere of praxis where science and philosophy must be counted as a particular form of theoretical practice. It is the 'universal field' in which we live, move, communicate, and theorize, and must be considered the ultimate foundation of any theory. It is objective only in that it is intersubjective, relating to the acts of those that inhabit it, but for every one of us it is pregiven, always already there. Even though the world of human life is characterized by great diversity, according to Husserl there are fundamental structures of sense that guarantee its unity – no matter how distant a culture may be from mine, there is always some common ground that lets me interact with its inhabitants. The lifeworld does not exist in the plural.

What was remarkable was Husserl's willingness to take intersubjectivity as a starting point, not as a result to be deduced from individual consciousness: the transcendental must be conceived as collective. Still, the question of mediation between the individual and the social that had not been solved in the *Cartesian meditations* remained a problem. In his *Phenomenology of the social world*, Alfred Schütz had provided a firmly Husserlian account of this mediation, taking individual consciousness as a starting point (Schütz, 1932). Even though the philosophical ambitions of the book are obvious, Schütz understood it as a contribution to sociology, and its scope is somewhat more modest than that of Husserl's *Crisis* where the lifeworld has no natural world or world of science beside it but is meant to encompass every kind of worldly phenomenon. The social world as Schütz analyzed it is a specific field within the world as such, and even when he later adopted the term lifeworld, this understanding remains in place (Schütz and Luckmann, 1973). His aim was to clarify Max Weber's concept of meaningful social action by an analysis of the genesis of meaning or sense in relation to the individual, the other, and society, effectively basing society on the individual. By distinguishing 'in-order-to-motives' and 'because-motives' as the sole types of motivation, Schütz significantly narrowed the range of possible descriptions and explanation of social phenomena. On this view, sense as the fundamental property of social action only comes into play in a retroactive explicit interpretation of one's own and the others' actions.

One might compare this position with the sociological works of Pierre Bourdieu (1971). Even though Bourdieu somewhat aggressively denounced philosophy, he relied heavily on the work of Husserl and especially Merleau-Ponty and developed a theory of the social world that has rather strong philosophical implications. His basic concept of 'habitus' as incarnated social meaning can be read as a sociological elaboration of the latter's notion of the lived body. As elaborated earlier, the body as Merleau-Ponty conceived it is not a given entity but rather our primary means of relating to the world. In this way it is shaped by its interactions just as much as by its innate structure, and the acquisition of skills like manipulating complex tools or playing a musical instrument must be considered as an extension and modification of it. In social interaction, the habitus shapes our way of acting, itself being shaped by previous interactions. The mediation between individual and society does not take place in the constitution and reconstruction of meanings as motives but in the incarnation and reenactment of social meaning by the habitus. Consequently, action should be considered as situated rather than subjective in the traditional sense. According to Bourdieu, social change is always possible because social action is never completely determined, but it is difficult because it is not a matter of mere reinterpretation of social meanings but has to deal with the inertia of the habitus.

The Other

In the phenomenological description of intersubjectivity and sociality presented so far, one aspect was all but absent: the active role of the other. In Husserl's as well as in Scheler's and Schütz' reconstructions, the other appears viewed from the perspective of the self, as someone who must be intuited or understood. Jean-Paul Sartre offered a different perspective. In his *Being and Nothingness*, the gaze of the other opens up a whole new dimension: it objectifies me and pins me down, as it were, transforming me from an essentially indeterminate and free subject into this particular bodily being that can be seen and defined (Sartre, 1943: pt. 3, Chapter 1, IV). Also, the other's gaze upon the world that for Husserl guaranteed its objectivity appears much more dramatic, as a radical reorientation of every object away from me and toward him. Even though Sartre's account of the gaze might seem overdramatized, his insistence on the irreducibility of my being affected by the other to my sphere of consciousness is an important contribution to phenomenology, reminding us that the inaccessibility of other minds might not be the only problem phenomenology has to deal with when it comes to intersubjectivity.

Emmanuel Levinas followed an even more radical path of inquiry. The other with a capital O as he construed him is not primarily an objectifying gaze but a face that issues a demand. In itself, this demand is unconditional, calling me into responsibility for the other in a way that I cannot evade or escape (Levinas, 1961). By describing this relation as primordial and irreversible, Levinas completely reinterprets the relationship between self and other as it was conceived by Husserl. Now it is not the Other who is dependent on me, being a vis-à-vis that I have to intuit or understand, but it is me who is exposed to the demand of his face before I can think of myself as a competent individual who can freely decide what he wants to concern himself with. Even if I am not bound by the demand I have to relate to it in some way, and even if in the end I turn away, I cannot deny it; Levinas speaks of non-indifference (Levinas, 1974: Chapter V 1. e). The primordial

relationship is not one of cognition, and the Other will not be made into an object and cannot be dealt with in the categories phenomenology has to offer – a fact that can only be stated in phenomenological terms.

The situation Levinas describes is one of radical asymmetry: even though he speaks of a face-to-face situation, the relation cannot be turned around so there would be a complementarity of perspectives, and neither is there a common category the other and myself can be subsumed under. The asymmetry in Husserl's version of intersubjectivity ran the other way, with the subject being the norm of the other and the locus, if not the agent of his constitution as other. Even so, there is a process of 'othering' of the self, as Michael Theunissen called it, leading to a situation where I am one among others (Theunissen, 1965: sections 11–14). For Levinas, there is no such operation of leveling myself and the Other, and his alterity is irrevocable. My responsibility stemming from his demand cannot be countered by my rights toward him. It is unconditional and has no natural bounds.

Following the tradition of Husserl and Heidegger, Levinas considered this theory of the other 'first philosophy,' i.e., heir to metaphysics, and contrasted it with ontology which suggests an order of being(s) that can be rationally ordered and comprehended. Ethics in the radical sense he gave it is the true first philosophy because the asymmetrical relation to the other is primordial in the sense that subjectivity and cognition of the world is based on it and it cannot be conceived in neutral terms.

Levinas' position entails some obvious questions concerning the possibility of ethics in the more mundane sense of how we are supposed to act in different situations and of politics as the art of balancing interests where the unconditional has no place. He himself speaks of the 'third party' with whose appearance the question of justice arises, but does little more than state the problem. Others have taken this lead: Burkhard Liebsch calls for a culture of hospitality, calling into question the primacy of rootedness and cultural identity in the face of others whose appeal is urgent and real (Liebsch, 2008). Simon Critchley has offered an interpretation of politics that stresses an ethics based on the Levinasian demand of the other as a potential element of unrest within the political sphere, persistently calling into question any established order, and as an inspiration for resistance and, finally, an anarchist stance (Critchley, 2007). Robert Bernasconi has pursued the topic of race and racism from a Levinasian background (Bernasconi, 2001). Bernhard Waldenfels has been following a different path, drawing on Levinas, Merleau-Ponty, and others to work out a phenomenology of the alien ('der Fremde,' which might also be translated as 'the stranger' or 'the foreigner') (Waldenfels, 1994, 2006). He adheres to the idea of an irrevocable asymmetry but insists on differentiating between different ways of being addressed or appealed to and different registers of responding. Still, there is always a gap between address and response, an element of discontinuity and belatedness or deferment that makes it impossible to simply fulfill a demand or to respond exhaustively. The Other as alien always escapes my attempts to pin him down, to understand him or, most importantly, to do him justice.

Phenomenology in its different varieties has made contributions to various fields of philosophy and related disciplines. Even though aspirations for developing a new version of first philosophy that the tradition has inherited from its founder Edmund Husserl have come to be viewed critically, its productivity remains unbroken. In philosophy, the topics of other minds, the body, the lifeworld, the Other, and others that could not be elaborated here have provided inspirations for thinkers from diverse backgrounds and continue to be a challenge today.

Abstract

A central task of legal philosophy is to provide a general explanation of the normativity of positive law. Legal positivist theories pursue this aim primarily by philosophical analyses (linguistic, conceptual, or ontological) that explain law by descriptive reference to social practices, mainly of institutional actors. For example, legal validity is explained by a rule of recognition, which is a social norm among legal officials. Naturalistic approaches in legal positivism seek a closer contact to the social sciences. Natural law theories deny that any explanation of law could succeed without reference to (true) political morality.

Since the beginnings of philosophy in ancient Greece, law has been the object of philosophical inquiry. However, classical natural law theories in the tradition of Plato, Aristotle, or Aquinas treated law as part of normative moral or political philosophy. In the modern age, with the emergence of nation-states and market societies, law increasingly became controlled by centralized political authorities and more separated from traditional morals and social customs. In the wake of these developments, a discussion on the concept or nature of 'positive law' emerged in legal philosophy. Jeremy Bentham not only dismissed inquiries into preexisting natural rights as metaphysical 'nonsense on stilts,' as is well known, but also developed a long unpublished analysis of law as commands (Bentham, 1970[1782]). The 'command theory of law' was later elaborated and published by Bentham's disciple and legal philosopher John Austin (1995[1832]). It became a prevalent view in Anglo-Saxon legal positivism and Austin's methodological maxim to keep descriptive analyses of law 'as it is' apart from normative inquiries into law 'as it ought to be,' remains the hallmark of legal positivism. Legal positivism was revived when H.L.A. Hart presented a more sophisticated analysis of law that drew on sociological hermeneutics and Hans Kelsen's 'pure theory of law,' an earlier version of legal positivism in the continental tradition (Kelsen, 1967[1960]; Marmor, 2010). Hart understood legal systems as a union of primary and secondary rules and introduced the distinction between the internal point of view of a participant in the legal system and the point of view of an external observer (Hart, 2012[1961]). Hart's seminal work sparked a debate between legal positivism and natural law theories over the concept or nature of law, which grew into an academic field of its own, with Roland Dworkin's interpretivism arguably being its most influential critique and alternative (Dworkin, 1977, 1986). Today this debate forms a major branch of the philosophy of law (or legal theory or jurisprudence, respectively) on which this article focuses. Normative inquiries into particular legal doctrines or specific areas of law form another branch of legal philosophy, which is not covered here.

Positive Law, Social Facts, and Morality

Positive Law and Social Practice

Legal orders are collections of norms, be it the law of nation-states, supranational entities or international law. All legal orders comprise norms that impose duties to perform or refrain from certain actions on natural persons or legal entities (primary rules). In most cases, legal orders also comprise explicit meta-norms on the creation, change, adjudication and enforcement of primary rules, in particular norms that determine legal powers, procedures, and legal personalities (secondary rules). Legal orders are often, but not necessarily, organized hierarchically, like the legal systems of nation-states, which are united by a common constitution and divided, e.g., into federal law, state law, municipal law. International law, however, with its imperfectly coordinated international regimes, often lacks hierarchical integration. Different to norms endorsed in ideologies or philosophical theories, legal norms are necessarily grounded in and emerge from actual social practices of particular collectivities. Without a social practice supporting it, positive law ceases to exist. Legal norms share this property with informal social norms, and like them, legal systems usually react to noncompliance with some form of explicit sanctions (McAdams and Rasmusen, 2007). But unlike social norms, legal systems are formal institutions administered according to rules by specialized legal officials acting in legal capacities on behalf of legally structured organizations like legislatures and courts. Norms of positive law are thus tied to the actual behavior of legal officials, often subject to deliberate change and confined to a particular jurisdiction. In this regard, positive law exhibits the characteristics of an observable social fact, located in time and space.

Normativity of Legal Norms

Participants in the legal system, however, tend to treat legal rules as genuine norms, not identical with the empirical social facts on which they rest. For example, lawyers often talk about legal norms as if they were entities with an existence of their own. To restrict a legal norm to a mere expression of an actual legislatorial wish combined with a credible threat, seems to reduce the full meaning of the term. Rather, legal obligations also provide intrinsic normative reasons for action. Following Hart, this stance toward the law is often called the internal point of view (Hart, 2012[1961]; Shapiro, 2006). Through this capacity to provide intrinsic normative reasons, legal rules appear to exhibit some characteristics that are usually ascribed to moral norms. Furthermore, lawyers often determine the content of legal norms

in light of normative principles, purposes, or values that are not explicitly stated in authoritative legal sources. And sometimes legal norms or judicial reasoning explicitly refer to standards like 'equality' or 'fairness' that appear to refer to (putatively) true moral norms. Thus, positive law also seems to be inherently interwoven with true morality. Hence, in tying together factual social practices with (possibly) genuine normativity, positive law appears to have a puzzling and seemingly dual nature.

Legal Philosophy, Science, and Political Philosophy

The specific contribution of legal philosophy to the explanation of legal normativity is controversial and should be viewed in contrast to other disciplines: Empirical explanations of the factual side of legal institutions are a matter of the social sciences and the philosophical questions pertaining to it should be addressed by the philosophy of science (Mantzavinos, 2009). The moral merits of positive law should be judged by normative political philosophy and meta-ethics. The content of concrete norms in particular legal orders, as it presents itself from an internal point of view, is discussed by legal doctrine, which may or may not draw on other sources like morality or scientific knowledge in varying ways and degrees. In contrast, the philosophy of law should, as far as this is possible, be concerned with providing general explanations of the normativity of positive law and its different aspects. In any such account, usually an explanation of law's relationship or nonrelationship to morality features prominently. This applies across topics, e.g., with regard to the basic elements and structure of legal orders, legal validity, the nature of legal obligation, legal interpretation and adjudication, etc.

Natural Law Theories versus Legal Positivism

Philosophical positions on these issues are usually perceived against the backdrop of the antagonism between legal positivism and natural law theories. In general, three explanatory strategies, either alone or in combination, are employed in this regard. In natural law theories, the normativity of legal norms is accounted for (1) by reference to normative, moral 'facts,' i.e., some version of a (possibly or purportedly) true political morality. In legal positivism, the normativity of law is (2) either explained by descriptive reference to social facts with 'normative' content like social norms (as in the approach of Hart and most other Anglo-American variants of legal positivism), or (3) the normativity of positive law is regarded as a stand-alone phenomenon that neither lends itself to explanations from social facts or moral norms, as the pure theory of law of Kelsen holds (Kelsen, 1967[1960]). However, despite their fundamental differences, legal positivists and natural law theorists often agree on the existence of many of the aforementioned, ostensibly moral characteristics of law. Real disagreement remains, however, with regard to the interpretation of these phenomena as either being explicable as social facts or as necessarily implying true morality. For example, Hart agrees with natural law theories that obligations stated in valid legal norms provide intrinsic reasons for actions, but he explicates these reasons as normative attitudes and hence mental states. Natural law theorists on the other hand insist that only true morality could actually provide normative reasons for actions. Thus, the main points of contention between legal positivism and natural law theories revolve around the extent to which descriptive or analytical accounts of positive law are methodologically possible, in substance successful, and, if so, also of interest (Dickson, 2012). Put differently, the discussion of the concept of law is to some extent a discussion about separating descriptive from normative questions in the philosophy of law.

The Validity of Law

The concept of validity is critical for any philosophical explanation of positive law. It is also a central issue in the debate between legal positivism and natural law and will be used in the remainder of this article to illustrate their respective positions. The concept of validity is also pivotal for the working mechanisms of positive law. Modern legal systems do not treat the content of law as given by nature, tradition, or religion, but explicitly allow for the creation and change of laws through willful actions of authorized actors as in the conclusion of international treaties, adoption and change of constitutions, legislation, and administrative rule setting or judicial law making via precedents. In consequence legal norms vary over time and between legal systems. The function of the concept of validity is thus to identify those legal norms that actually 'exist' in a particular legal system. Attributed to a norm, legal validity implies its existence as a legal norm, membership in a particular legal system, and normativity or binding force. The concept of legal validity is relevant, i.e., for two different but interconnected problems of positive law: (1) the foundation problem, i.e., what the ultimate grounds of validity are, and (2) the specification problem, i.e., how the actual content of a particular legal system is determined, e.g., by statutes or precedents. Differences between legal positivism and natural law theories over the role of social facts versus true morality play out differently in both problems. In general, with regard to ultimate validity differences between them, the two approaches tend to be more categorical; whereas with regard to specification, they are rather like different ways of accounting for identical features.

Legal Positivism

Separation Thesis

Legal positivist theories hold that the existence and content of law depends on social facts only, not on its merits (Green, 2009). That does not exclude some legal positivists from acknowledging certain contingent or even necessary connections between law and morality (Gardner, 2001). But as far as the validity of legal norms is concerned they endorse the separation thesis. Legal positivism thus strives to account for the normativity of law by reference to social facts. Some legal positivists nevertheless admit certain apparently moral properties in law like the presence of normative principles, purposes, or values in legal reasoning, explicit references to morality, or the perception of legal obligations as intrinsic reasons for actions. But these phenomena are interpreted in a descriptive manner as facts about the law that can be explained by or as social facts. For example, Austin explains the obligation contained in a legal norm with the actual behaviors of threatening sanctions and

habitual obedience. Hart criticizes this reduction as inadequate because, as he contends, from an internal point of view legal obligations are perceived as intrinsic reasons for action. But for Hart the internal point of view does not necessarily rest on good moral reasons to obey the law but on an empirical attitude that accepts law as a standard of conduct. This does not imply that legal positivists always deny the possibility of a true political morality. In fact, Austin believed in Divine law and Hart held moral realist convictions. But legal positivists have to insist that morality is not necessary for such an account, at least as far as the existence and content of law are concerned.

Validity in Legal Positivism

Pure Theory of Law

Most radically perhaps, the pure theory of Hans Kelsen denied that the normative validity of legal systems could be derived from either social facts or from true morality without violating Hume's Law or running into an infinite regress. For Kelsen, validity is ultimately grounded in what he calls a 'basic norm' (Kelsen, 1967[1960]; Marmor, 2010). This basic norm, however, is neither a social norm nor a norm of Divine or natural law; it is not even a real norm but only a presupposition lawyers necessarily make in reasoning about law. Thus, for Kelsen, legal validity is merely hypothetical or 'transcendental.'

Command Theory of Law

Anglo-American legal positivists, however, tend to have no objection, in principle, to locating the ultimate source of legal validity in social facts, namely in social practice with normative content. Rather than tackling the general philosophical problem of how a legal 'ought' could be derived from an 'is,' Anglo-American legal positivism rather focuses on the substantive analysis of the social practices from which legal systems emerge. Before Hart, the prevalent account was Austin's version of the command theory, according to which positive law consists of the commands of a sovereign (Austin, 1995 [1832]). The sovereign is a person or a group that receives habitual obedience from the majority of society but is not in the habit of obeying anybody else. Legal norms are a particular type of command issued by the sovereign, namely general and public orders backed up by the threat of sanctions. The sovereign's capability to produce norms rests in his ability to command the obedience of his inferiors by exercising power. It is widely assumed that Hart demonstrated the inadequacy of this account (see Schauer, 2010). For example, in many legal systems there is no single sovereign with ultimate powers. Also, the concept of sovereignty can hardly account for the restrictions that constitutions impose on law-making powers. But first and foremost, in legal systems, ultimate authority is defined by rules rather than preceding them.

Hart's Concept of Law

In his own account Hart replaced authoritative orders with rules as the essential element of law and introduced the distinction between primary and secondary rules. Primary rules impose duties on people and thus perform the function orders have in Austin's account, whereas secondary rules govern the creation, change, and administration of rules. Thus, legal systems usually comprise secondary legal rules that explicitly regulate the creation of valid legal norms, be it primary rules or lower-level secondary rules. They do so by determining legal procedures and competences which have to be observed for such changes to be acknowledged as actually creating new or changing existing law. Rules granting such powers are often stated explicitly in foundational or supreme legal documents like constitutions or the EU-Treaties or they may be the subject of customary law at this supreme level. Validity is an intrasystemic matter regarding the proper application of power-conferring legal rules, i.e., a legal question to be addressed by legal doctrine.

However, the ultimate source of legal validity, i.e., the validity of the legal system as such, cannot be derived from legal rules without circularity. To account for the ultimate validity of a legal system, Hart introduces the rule of recognition. The rule of recognition is a secondary norm that exhaustively specifies the criteria for validity in a given legal system. Thus a legal norm is valid if it satisfies all the criteria specified in the rule of recognition. However, the rule of recognition itself, as the ultimate source of validity, is not a legal rule, but a social rule among legal officials. It functions, so to speak, as an 'empirical basic norm' that gives positive law a conventional foundation in the social practice of legal officials. This concept is widely accepted in legal positivism, in principle, but considerable debate remains as to the exact nature of the foundational social norm. Hart conceived the rule of recognition as a 'social rule' which is accepted as a common standard and the violation of which is met with criticism. Alternatively it has been proposed to regard the rule of recognition in game theoretic terms as a coordinating convention (Postema, 1982), as a constitutive convention (Marmor, 2009), or in terms of the theory of joint intentionality as a shared plan (Shapiro, 2011). The questions of whether the rule of recognition only addresses judges or also other legal officials, and whether it provides legal officials with authority and/or puts them under a duty to apply the rule of recognition also remain points of contention. There is also a discussion, sparked by Ronald Dworkin's critique, on whether the idea of a rule of recognition can be reconciled with dissent among legal officials over the content or proper application of the rule of recognition.

Inclusive versus Exclusive Legal Positivism

The establishment of positive law as an institution that is clearly set apart from other informal types of social institutions like social customs or traditional morals, is a hallmark of modern legal systems. A major way to bring this about is by adopting secondary rules that organize the formal creation and application of legal norms through specific legal bodies, procedures, and forms, as is the case with parliamentary legislation or judicial precedents. In this way, valid legal norms can be traced back to observable and easily identifiable sources. Put differently, valid legal norms are singled out by originating from a competent body invested with legal authority and following the required procedures and formalities. However, not all legal norms can be traced back to such formal sources. Many national legal systems, as well as international law, adopt customs that are widely observed in practice as customary law if they meet certain requirements specified in the jurisprudence of courts or legal doctrine. Many legal systems also regard some general normative principles as legally binding, even if they are not

explicitly stated in authoritative legal sources but rather inferred as implicitly underlying them. And in many legal systems, judges, under certain circumstances, may make reference to what they regard as morally true without these moral truths being explicitly laid down in positive law. In all these cases positive law seems to include social, implicit, or moral norms that, as such, are not the product of formal law creation and hence lack the institutional pedigree that is typically associated with positive law. On this basis, Dworkin dismissed the rule of recognition as being incapable of accounting for nonsource-based norms and, in particular, for legal principles.

Legal positivism's reaction to this criticism was to split into two camps, exclusive (or hard) and inclusive (or soft) legal positivism. Exclusive legal positivism insists that norms of positive law have to be based on authoritative sources. Nevertheless, the rule of recognition may empower legal officials to treat customary law, legal principles, or moral arguments as part of the law. This, however, does not include social or moral norms among the sources of law, but rather confers the authority (and often the discretion) on judges to make reference to extralegal norms and thereby create new law. The judicial decision is hence to be regarded as the source of positive law, not as the custom, principle, or moral norm. Inclusive legal positivism, on the other hand, takes a more lenient view of the rule of recognition. According to this view, the rule of recognition may include social or moral norms in the sources of law. For example, the rule of recognition could include a proviso that grossly unjust statues are void *ab initio*. Thus, in its inclusive version, practical differences between legal positivism and natural law theories almost vanish. The ultimate explanation conditioning legal validity on morality, however, would still be categorically different: the inclusion of morality rests in the first instance on a contingent consensus among legal officials, in the other on a necessary connection of positive law with true morality.

Natural Law Theories

Moral Realism and the Connection Thesis

Many, but not all theories in normative political philosophy suggest normative standards of political morality that are intended for, or could be applied to the evaluation of positive law. Classical natural law theories find these normative standards in putatively universal moral norms that exist independent of human will and recognition (Aquinas, 2006 [1265–1274]), a view that implies ambitious epistemological and metaphysical assumptions. Modern accounts of political morality tend to avoid them and would rarely be counted as natural law theories in political philosophy. Natural law theories in legal philosophy, however, are defined more specifically as a particular thesis about the relationship between positive law and political morality. Natural law theories in legal philosophy specifically hold that positive law, as such, cannot be properly explained for methodological and/or substantial reasons, without reference to true political morality. Natural law theories thus include two elements: (1) they endorse a substantive position on political morality with regard to the law ('natural law') and thus assume at least the possibility of true political morality (moral realism), and (2) they endorse a thesis about a necessary connection between that morality and the validity and/or content of positive law (connection thesis).

Of course, natural law theories differ widely regarding the kind of 'natural law' they endorse. Some argue on the basis of classical natural law theories and some rely on modern accounts of political morality. For example, John Finnis defends an Aquinian account of natural law that presumes an universal, mind-independent, natural law (Finnis, 2011[1980]). Other modern natural law theories adopt the connection thesis but do not argue for a universal political morality. These approaches are sometimes labeled 'non-positivism' to set them apart form classical natural law theories. By far the most influential non-positivist theory is Ronald Dworkin's interpretivism (Dworkin, 1977, 1986; Stavropoulos, 2014). According to Dworkin, law is an interpretive social practice defined by the aim to legitimate the use of coercion. To fulfill this function, law necessarily includes moral standards that are not mere social facts but, in principle, capable of actually providing the required legitimization. But in contrast to universal natural law these moral standards are not independent from the social practice, but inherent to it (Stavropoulos, 2014). A constructivist natural law theory that is also metaphysically unsuspicious has been proposed by Robert Alexy. It holds that law necessarily claims to be legitimate – a claim that has to fulfil certain criteria of 'correctness,' to be redeemed in political and legal discoursest (Alexy, 2002).

Validity in Natural Law Theories

Morally Defined Function of Law

Natural law theories jointly accuse legal positivism of overlooking the moral assumptions necessarily inherent in positive law. This criticism may be based on purely descriptive–analytical grounds, on grounds of normative political philosophy, or both. Often, it is based on the (descriptive or normative) claim that law is (or should be) an institution that is defined by its function (i.e., a 'functional kind'), and that this function is necessarily moral in nature (Moore, 1992). For example, traditional natural law theories view the purpose of law as the promotion of the common good, modern contract theories tend to find its purpose in guaranteeing individual rights or justice, and Dworkin sees the purpose of US Law in the justification of state coercion. Some natural law theories take functions to be universal, whereas in interpretivist or constructivist versions, moral functions may be restricted to the social practices of a particular community. On both accounts, however, it is regarded as a necessary property of positive law not only to pretend but to actually fulfill its moral functions, at least to a certain degree. If this assumption were true it would seem impossible to explain positive law without reference to true morality. With regard to legal validity, the connection thesis implies that social practices cannot provide sufficient and/or exhaustive grounds for legal validity. Instead, the connection thesis holds that legal validity, in general or in specific contexts, depends on true morality. This is rarely taken to imply the extreme view that legal validity is conditional on full conformity with political morality. Rather, noncontradiction with some fundamental tenets of political morality is required. For example, after World War II, Gustav Radbruch posited what came to be known as the 'Radbruch

Doctrine.' It claimed that grossly unjust laws should not be acknowledged as legally valid; and laws that did not even attempt to bring about justice should be denied the quality of law altogether (Radbruch, 2006[1946]; Alexy, 2002).

Social Facts and the Specification Problem

However, none of these natural law theories denies the relevance of social practice. Rather, they ascribe to social facts the role of fixing the specific content of legal norms within the confines of political morality. Social facts could, for example, serve to adapt universal natural laws to the circumstances obtaining in a particular jurisdiction. In an interpretive account, facts about institutional legal practices are needed in order to infer the moral claims inherent in these practices. Nevertheless, for interpretivism, facts about institutional practices are insufficient to account for the specific content of law, because the content of law is determined by what follows from principles that best explain and justify past institutional practices. On both accounts, social facts are insufficient to account for the validity of positive law.

Methods

Two different kinds of methods (or some combination of them) can be employed in arguing for a concept of law, descriptive methods of philosophical analysis, or normative methods of political philosophy. Although descriptive methods dominate in legal positivism and normative methods are common in natural law theories, methods and substantive positions do not line up perfectly. For instance, legal positivism is sometimes defended on normative grounds as well, e.g., because a positivist concept of law is thought to foster legal certainty and strengthen the rule of law. Proponents of natural law theories, on the other hand, often argue that legal positivist theories fail to account for important features of law even on purely descriptive–analytical grounds. In this vein, Dworkin criticized Hart's notion of a rule of recognition as being incapable of explaining the presence of unwritten legal principles. The methods of normative political philosophy are beyond the scope of this article. A brief discussion of descriptive analyses, however, is warranted because it is not self-evident why explanations of positive law that employ references to social facts are philosophical in nature. All social facts that legal positivist theories draw on could be the object of study in the empirical social sciences, e.g., sociology of law, legal psychology, or economic analysis of law.

Linguistic Analysis

From the publication of Hart's 'Concept of Law' until not long ago, legal philosophy usually has been set apart from social science approaches by its philosophical method of a 'linguistic analysis.' Hart himself described his method as being both 'analytical jurisprudence' and 'descriptive sociology' (Hart, 2012 [1961]: Preface iv) and quoted 'ordinary-language' philosopher John Langshaw Austin, stating that "a sharpened awareness of our words" may be used "to sharpen our perception of the phenomena" (Hart, 2012[1961]: p. 14). Thus it was a common assumption that Hart was committed to 'ordinary language' philosophy and that the reference to sociology rather referred to the empirics of language usage. In 'ordinary language' philosophy, an analysis of the concept of law would imply an analysis of the ways in which the word 'law' functions in rule-governed linguistic practice among competent speakers of a natural language ('language games'), based on observations of that practice and purportedly shared linguistic intuitions (Marmor, 2013). But by now there seems to be broad agreement that few philosophical insights emerge from tracking the meaning of the word 'law' in our linguistic practices and that, contrary to Hart's own insinuations, linguistic analysis was neither the kind of philosophical analysis he actually undertook nor the analysis that legal philosophy should pursue. In any case, as a substantive thesis on legal orders and their relation to morality, legal positivism is not committed to a particular method and is compatible with different semantic, ontological, or epistemological positions.

Conceptual and Ontological Analysis

The method that should replace linguistic analysis is a subject of current debates (Coleman, 2002). The question concerns not only the method but also the proper object of legal philosophy. With regard to the latter, Josef Raz proposed that instead of the 'ordinary language' meaning of law, legal philosophy should study law as part of the 'self-understandings' of a society (Raz, 2005). The concept or nature of law thus does not refer to the institution of law as such but to a society's self-understandings with regard to law (Marmor, 2013). Alternatively, law itself, i.e., the empirical social institution grounded in communication, behavior, and mental states, could be the object of analysis. Since shared beliefs and attitudes may play a vital role in constituting law and thus be part of the ontology of this social institution, analyses of shared self-understandings may also be involved in the analysis of law as a social institution (Leiter, 2013b), although they do not exhaust it. No consensus exists, however, as to what the analyses of either type would imply in terms of philosophical methodology and how these would differ from methods of empirical social sciences. Nonlinguistic, conceptual, or ontological analysis and methodological naturalism are two important candidates, so far.

Appropriate methods of nonlinguistic analyses depend on their subject and aims. If the purpose lies primarily in identifying, clarifying, and/or enlightening the societal concept of law, it might strive to remove ambiguities and contradictions, make implicit assumptions explicit, and/or eliminate implausible metaphysical presuppositions. If conceptual analysis aims at an ontological explanation of the phenomenon itself, it might seek to identify essential, or at least, important general properties of law. Such an analysis could imply, for example, breaking up the complexities of legal orders into simpler conceptual elements (e.g., imperatives, primary and secondary rules, or basic concepts) or into ontologically more fundamental phenomena (e.g., social norms, conventions, or joint plans) or working back to prior principles (e.g., to the separation of law from morality). In this vein, Andrei Marmor proposed a reinterpretation of Hart as a reductionist analysis of law's essential properties (Marmor, 2013). Sometimes intuitions are advocated as the specific kind of evidence philosophical analysis should draw on. But in legal

philosophy it is questionable how intuitions could help to establish descriptive adequacy, once the realm of linguistic analysis is left. Analyses in legal philosophy rather seem to rest on empirical generalizations and can thus hardly claim the self-evident, a priori necessity invoked in other areas of philosophy. Rather than purporting to show necessary or even essential properties of law, legal philosophy might be content with demonstrating general, important, or characteristic features of positive law. Also, legal philosophy might keep closer contact with the social sciences, as Hart was influenced by the sociological hermeneutics of Max Weber.

Naturalism in Legal Philosophy

Reliance on the social sciences is taken one step further in philosophical naturalism. According to methodological naturalism, philosophy should proceed in continuity to the empirical sciences by emulating their methods and/or drawing on their results (Leiter, 2012). Usually this implicates the natural sciences, but in case of legal philosophy the focus lies on the social sciences. Naturalism could mean replacing philosophy with science or locating philosophy at the highly abstract, conceptual, or foundational end of science. Both approaches may, however, be incapable of addressing questions pertaining to the relation between law and true morality, since true morality is beyond the purview of scientific methods. But naturalism may be apt for explaining the relationship between the law's normativity and the social facts it is grounded in. Questions such as these were addressed from a naturalistic point of view in Scandinavian legal realism (Leiter, 2013a). According to Axel Hägerström's austere naturalism, only natural things exist and concepts that do not refer to observable facts are meaningless (Hägerström, 1953). Accordingly, legal concepts like 'duty' or 'right' are dismissed as meaningless and the normativity of law remains a 'mystical force,' since it does not exist in the real world. In this extreme view, legal doctrine – much like theology – is accused of talking nonsense about nonexisting objects. Alf Ross later gave an influential naturalized account of law that acknowledged the normativity of legal norms and explained their binding force in terms of behavior and mental states (Ross, 1959). Normativity, in his view, rests in the fact that legal norms are observed with a psychological sense of obligation. These early naturalist approaches to legal philosophy were heavily criticized by Hart and naturalism largely fell into disfavor until it was brought back to the forefront by Brian Leiter (Leiter, 2007). He argued, for example, that the central tenets of legal positivism, and in particular those of Hart, are best interpreted in naturalist terms (Leiter, 2013b).

Reductionism, Eliminativism, and Emergentism

Leiter and Marmor explain (1) legal norms by reference to underlying social practices and (2) social practices by reference to behavior and mental states. In doing so both offer reductionist theories, because they assert that one set of phenomena can be accounted for by another set of phenomena (Marmor, 2013). But they differ in the methodological justification of their account, i.e., whether they attribute the success of their explanation to philosophical analysis or to compatibility and continuity with social sciences. The second aspect of reducing social phenomena to behavior and mental states concerns the well-known dispute between individualist (reductionist) and holistic (emergentist) theories in social science. Critical with regard to the success of reductionist legal positivist theories, and disputed in legal philosophy, is the possibility of reducing law's normativity to social norms. In general, three possible relations can be drawn (O'Connor and Wong, 2012) between legal norms and social practices, and each could be thought of as either an epistemological or an ontological relation: First, an eliminative reduction would regard the normativity of law (or some aspects of it) as ontologically inexistent or epistemologically inaccessible to rational analysis, as Hägerström's radical legal realism did. Following this reasoning, there is nothing that needs to be explained. Secondly, one could assert that legal norms exhibit properties like 'validity' or 'normativity,' but hold that these properties can be fully explained by underlying social practices (like microeconomics explains aggregate outcomes in terms of individual behavior). This seems to be the kind of reductionism implied by Leiter and Marmor. Thirdly, one could hold that 'validity' or 'normativity,' as properties of legal norms, cannot be fully explained by social facts, either because we lack the knowledge necessary to do so or because normativity is an emergent and hence irreducible property that ontologically supervenes on the respective social practices. Then reductionism would fail. But this would not necessarily mean that legal positivism is wrong and a natural law theory true, because the irreducible property does not have to consist in true morality but could just be the normativity of law. Of course, different aspects of legal norms could require different versions of reductions. For example, it is a plausible view that legal norms do not exist as incorporeal entities but that they do exist as aggregates of behavior and mental states.

Abstract

Since the Ancient Greek origins generally considered as the inception of philosophy, questions relating to self, identity, mental illness, and norms have been the focus of many scholars. Ancient concepts have been refined through the Middle Ages and by contemporary philosophers. Modern psychiatry and psychology can be influenced by philosophical concepts, which can aid patient-centered care, the development of service delivery methods, research, training, and to foster an international community aligned for the advancement of patient care and the sharing of knowledge.

Introduction

An understanding of philosophy is central to insightful practice and appreciation of the work of psychologists and psychiatrists. In fact, independent philosophical concepts are the only way of answering some complex questions in the field. How can we define the nature of the psyche? What is disturbed psychic experience and what do we mean by illness and normalcy? As the mind–body problem purports, does the psychic form part of the material, or is it autonomous, following independent laws of its own? Does inner psychic experience exists and is it accessible by means of introspection, or as behaviorism suggests, should we only describe visible behavior? Is the essence of the psychic found in the active relationship of the 'I' to the 'You,' to the other (intentionality), and is it indeed only comprehension of the other, via *mimesis*, that constitutes one's own psychic experience? These are the sorts of questions posed by philosophical psychology, by psychiatric anthropology, and they can only be satisfactorily tackled if we understand the development of philosophical thinking.

From the very beginning, scientific psychiatry has raised fundamental questions within the fields of philosophy and psychology, namely as regards the nature of the 'psyche' and the concepts as to what constitutes mental illness. The question of what it means to say that something is 'psychical' leads to speculation in psychiatry insofar as special heuristic aspects are involved and this can be explosive if one professional group feels excluded by a certain definition or approach.

While there is on-going debate around psychopathology, pathology and the definitions of key psychiatric concepts, psychiatry has been criticized both internally and externally as being 'unscientific' (Phillips, 2000) and mental health professionals suffer at least part of the stigma that is projected by wider society onto psychiatric patients. Fulford, Stanghellini, and Broome make a compelling argument against these criticisms. They suggest that philosophy can be used to prove that mental health care delivery is both more challenging than other areas of health care and also that psychiatry leads the way among medical fields who are yet to encounter the kind of epistemological and philosophical debates that punctuate daily practice in psychiatry (Fulford et al., 2004). They suggest five key ways in which philosophy can aid practice in mental health care – patient-centered care, supporting new methods of service delivery, advancing research in neuroscience, psychiatric training, and supporting an 'open,' international society of psychiatrists – which shall be expanded on later in this article (Fulford et al., 2004).

Philosophical Psychiatry

In accordance with Brentano's basic idea that the psychical can be identified with the 'intentional' (Brentano, 1874), one might argue that psychiatry is so important to philosophers because the disturbances of intentionality in various domains of the mental world of humans are what might be termed as 'negative images' of the psychic functions, which normally operate in the human mind. The special method by which Karl Jaspers (Jaspers, 1913) elaborated this view of the human mind is the 'phenomenological approach' to various kinds of disturbances of mental functioning in psychiatric patients (deficiency model of psychic dimensions in Jaspers's *General Psychopathology*).

However, this is not the only way in which the relationship between psychiatry and philosophy can be construed. The other aspect is the issue of the potential role of 'normalcy' in social life. As a fluctuating criterion for assigning people to a psychiatric context, normalcy cannot be regarded as a phenomenon of 'average' and represents merely the concept of 'ideal typology' (Blankenburg, 1971). From a philosophical point of view, the subject of psychiatric 'normalcy' constitutes a major problem, since it raises the issue of the existence of an 'individual norm' in the sense of the 'alterity of the other' (Lévinas, 1987). Seen in this way, psychiatric disorders are not simply 'defects' but represent variants of normal psychic life which – when exaggerated – are interpreted as disorders and treated by psychiatrists.

This concept fits in with the approach of evolutionary psychiatry, which considers that psychiatric disorders have evolved because they relate to psychic functions which – in their submaximal expression – yield advantages where natural selection is concerned. Viewed in this way, as Blankenburg (1971) suggests, psychopathology does not constitute a 'statistical, average norm' but an 'individual norm.' In a similar sense, Spaemann and Löw (1981) have argued that health itself contains a teleological notion: "If 99 percent of the population suffered from headaches, headaches still would not be 'normal'." Philosophical concepts in psychiatry, therefore, have

to address the problem of 'normalcy'; they face the difficult challenge of acknowledging deviant cognitive and mental events merely as expressions of the alterity of the other.

Greek Philosophy: Hippocrates, Socrates, Aristotle, and Plato

A full understanding of philosophy is not possible without, at least, a basic awareness of the Greek founding fathers of philosophy – Socrates, Aristotle, and Plato. The famous physician, Hippocrates, is also an important figure who shaped modern medical practice. He was the first thinker to propose that disease was caused naturally by a constellation of environmental and living factors, rather than being a punishment for sin (Adams, 1891); was credited with first propositioning the humoral approach to disease causation incorporating psychological dispositions (Chadwick, 1983) and proposed the seminal Hippocratic Oath, which sought to ensure that doctors practiced in a respectful, professional, and beneficial way toward their patients.

The focus of Greek philosophy more widely is on the individual thinking and acting intentionally, and self-reflection is thus the cornerstone of ancient Greek thought. On the basis of the hypothesis of quasideterminism, the Athenian philosopher Socrates (470–399 BC) asserted that the will responds to the dictates of reason. He was puzzled and perplexed by the question of 'how should one live?' (Robertson, 2009). He developed the Socratic – or 'maieutic' – method, which elicits truths that lie hidden in an individual's unconscious by means of a process of question and answer. This method – in a completely different context – later became the basis of Sigmund Freud's psychoanalysis and the nondirective psychotherapy of Carl R. Rogers. The concepts proposed by Socrates are also central to professional ethics, and the answer to how one should live has evolved to incorporate a set of values. For psychiatrists, there are particular professional values that society both deserves and expects, as elicited by the World Psychiatric Association (World Psychiatric Association, 2011) and national bodies such as the United Kingdom Royal College of Psychiatrists (Royal College of Psychiatrists, 2014).

In works including his *Phaedo*, Socrates' disciple Plato (427–347 BC) differentiated between the spiritual and material worlds and applied this dichotomy to man by postulating that the psyche (soul), together with its logical functions, possesses a preexistence before the birth of the individual and survives into immortality (Plato, 1966). In *Timaios*, Plato defines madness (*manteia*) as a disturbance of the vegetative components of the soul (which he felt were located in the liver) but in the later *Phaidros* he tells us that the Gods can also send madness as an elevating spiritual force. The aim of Plato's philosophical psychology is to create harmony between the different psychic activities. Whereas Plato's idealism defines ideas as the only true reality, his pupil Aristotle (384–322 BC) based his psychology partly on empirical investigation, thus representing a type of *realism*. In his systematic discussion *De anima* (*On the Soul*), Aristotle describes the soul as the *entelechy*, the self-contained purpose of the body. This purpose must be fulfilled in order to achieve *eudaimonia* (human flourishing). In Aristotelian thinking, philosophical self-reflection leads to psychological self-actualization, and in his *Ethica Nikomacheia* Aristotle states that the purpose of ethics is not knowledge but action (Aristotle, 1984).

Although Aristotle was the most systematic Greek philosopher and had an enormous influence on the development of modern science, the treatment of psychological matters in post-Aristotelian Hellenistic philosophy is often described as eclectic. Stoic and Epicurean philosophy, in particular, must be considered as practical psychology. Given that the increasingly urbanized Hellenistic world had a greater resemblance – in some ways – to modern society than the Middle Ages, this practical psychology is still of interest. Epicureans and Stoics tried to find ways to alleviate anxiety, but their anxiety seemed to be more drived by the disturbance caused by a complex, fragile society than fear of God. Epicurean and especially Stoic thinking played an important role in Hellenistic culture and can thus be viewed as the first widespread popular psychological fashions.

After the fall of the Roman Empire, Christian Europe lost sight of some of Aristotle's major works. The philosophical psychology of the dominant neo-Platonism referred back to the static aspects of Platonism, shifting away from rationalism to metaphysical speculation on the relationship between a tangible and an intangible world, between the soul and God. St Augustine (CE 354–430) attempted to synthesize neo-Platonism with Christianity. Following on from Seneca and Plotinus, he leaned toward introspection as his philosophical and psychological method, considering that – alongside objective observation – self-observation of inner mental processes could function as the basis of knowledge. He, therefore, chose self-reflection as the basis of his epistemology, arguing that doubt presupposes the existence of the doubter (Augustine, 1984), an idea that later became extremely influential as Descartes famous *Cogito ergo sum*, more popularly known as the phrase, 'I think therefore I am.'

Metaphysics of Middle Ages and the Mind–Body Problem

The philosophical psychology of the Middle Ages was metaphysical and also deductive. The changeability of the soul and of world were interpreted philosophically as an inevitable but inferior property of the unchangeable, and consequently Christian dogmatism and neo-Platonism showed less interest in the experience of psychological interaction. With the foundation of the first universities from the thirteenth century onward, the process of philosophical debate increased and a more dynamic philosophical psychology developed as Aristotelian thinking was resuscitated through the medium of Arab philosophy. St Thomas Aquinas (1225–74) attempted to integrate Christian dogma with elements of Greek and Arab philosophy. Aristotle differentiated between an active, immortal intellect and a merely passive, understanding one. Aquinas accepted this view, describing the intellect as a passive power, a *tabula rasa*, which had to be filled with experience by the five exterior senses. In addition, there exists a rational power – which makes free will possible – and the soul also has vegetative components. In contrast to the neo-Platonic dichotomy of soul and body, Aquinas attempted to define

man as a psychophysical unity, as a body inspired by a soul. Taking his lead from Aristotle, Aquinas defined the soul as the form of the body and as an immortal spiritual entity. According to this theory, the body of a dead person consists of the same material or substance as that of a living person. As a result of this dichotomy, it is impossible to describe the impact of mental acts on real action without becoming entangled in serious logical difficulties. This is the *mind–body problem*: the issue of whether or not the soul or mind is an incorporeal substance, a nonmaterial entity obeying laws other than those, which govern the material world. Discussion of this problem has continued until the present day.

Modern Philosophical Psychology

Modern philosophical discussions related to psychiatric problems from the outset. René Descartes (1596–1650) reflected on the fundamental nature of illusions and the constitution of reality. He compared the reality of dreams with the consciousness in wakefulness. In his *Meditations on first Philosophy*, Descartes arrived at the irreducibility of the cogito, putting an end to the infinite regress of doubt about possible realities (Descartes, 1996). As a consequence of this concept, the modern subjectivistic understanding of consciousness has evolved, leading to the split between *cogitatio* and *extension* (soul and body), between the mental and the physical world, a split which represents one of the irresoluble problems in psychiatry.

Refuting earlier deductive speculation, the empiricist Locke (1632–1704) again emphasized the Aristotelian view that the human mind is like a blank sheet of paper and that all the material of reason and knowledge comes from observation, experience, and reflection. David Hume (1711–76) described ideas as the copies of sensory impressions. Most of our beliefs go beyond current impressions, but all that we can be certain of is perception, meaning that it is impossible, for example, to comprehend the *self* as a separate identity. Radicalizing this point of view, the positivism of Comte (1798–1857) postulated that the sensible comprises the whole range of knowledge and that any knowledge that cannot be comprehended by the senses must be rejected.

Immanuel Kant (1724–1804) speculated about constitutional aspects of psychiatric disorders. In his *Critique of Pure Reason*, he tried to deduce the a priori conditions of the possibility of experience (Kant, 1974). This type of categorical analysis of mental life has been decisive for all subsequent philosophical considerations about the formation and constitution of subjectivity and consciousness.

In this sense, idealism represents one of the possible forms of reactions to Kantian philosophy. For example, Georg Friedrich Hegel (1770–1831) developed an ontological approach to intellectually reconcile all elements of existence with one another within a systematic structure in which all contradictory moments of reality appear as dialectic mediations of the universal mind (Hegel, 1973). The philosophical psychologist Franz Brentano (1837–1917) elaborated a comparatively modest conceptualization of the difference between the mental and the physical, thereby developing a fundamental concept of philosophy of the psyche, namely the concept of 'intentionality.' In his work *Psychology from an Empirical Standpoint*, he argued: "Each mental phenomenon is characterised by what the scholars of the middle ages called the intentional (also probably mental) inner existence … of an object, and which we … would call the reference to content, direction toward an object" (Brentano, 1874).

One may argue that the main characteristics of psychiatrically ill patients are disturbances of intentionality. Thus psychic functions are 'intentional' insofar as they refer to an ('internal') object; they can 'mean' or refer to something. If this fundamental function of mental life is disturbed, a psychiatric disorder can be anticipated.

The Danish philosopher Kierkegaard (1813–55), deeply aware of Hegel's philosophical concept of the absolute and at the same time vigorously writing against it, developed a concept of subjective reality, prestructuring the later existentialistic conceptualizations of subjectivity, defining it as synthesis of soul and body, carried by spirit. His pioneer work about personal freedom formulated the questions as to *The Concept of Anxiety* (Kierkegaard, 1980). As has been pointed out by Hersch (1989), these basic ideas are represented by 'existence' and 'moment,' in which the subject works through to the moment of the 'reality of freedom,' the condition of 'anxiety.' That means that 'anxiety' cannot be understood primarily as an emotional state, but rather an existential condition, an intensified form of existence, leading to an autonomous subject ('choosing the self'). In this context 'Phenomenological reduction' has to be understood as the attention to the 'nature of the condition of things' and thus the 'things as phenomena.' A great and far-reaching concept in philosophical psychology, the philosophy of the 'language game,' has furthermore been elaborated within the philosophy of language by Wittgenstein (1898–1951). Jaspers has pointed out the importance of philosophy of language as the 'work of man.' The universals of language also play a role in the philosophy of Gehlen (1904–76) who referred to man as a 'nondetermined animal,' whereby Gehlen interprets the human nature as creating its own world as an 'open world' (Gehlen, 1987). Of special importance for psychiatric philosophical psychology is the concept of Helmuth Plessner (1892–1985) who developed the idea of 'positionality' of human subjects. Whereas animals show a 'centered positionality,' human beings live, according to Plessner, in an 'eccentric positionality' (Plessner, 1970). This concept plays a relevant part in psychiatric psychopathology, since disorders like delusions of reference and persecutory ideas may be interpreted as a disordered eccentric positionality (Emrich, 1992). In Jean-Paul Sartre's (1905–80) *Being and Nothingness*, the 'decentering of the world' plays a fundamental role in the phenomenological analysis of the 'glance' (Sartre, 1996). Sartre's analysis of the interpersonal relationship ends up in an intersubject fight of 'glances.' Later Emmanuel Lévinas (1905–95) acknowledged the 'otherness of the other' in the dimension of 'face': "The epiphany of the face is itself a word of honour in a certain way" (Lévinas, 1987). This view of responsibility in the interpersonal encounter is of great importance in psychiatry, stressing the importance of empathy in therapeutic relationships.

As a new academic discipline, psychology was obliged to assert itself against the established materialist sciences, especially medicine and biology. Positivist thinking consequently led to

strongly antimentalist and anti-introspectionist tendencies. The theory that it is only via *objective* observation that scientific method can formulate hypothetical laws from which it can then derive deductive arguments led to the radical behaviorist position that nothing that is the product of *subjective* introspection can be accepted. Positivism thus reduced psychology to a science that aims to predict and control behavior. Watson (1878–1958) and Skinner (1904–90) lead to academic psychology drifting away from philosophy, becoming more practical than theoretical and less concerned with understanding behavior (Watson, 1998; Skinner, 1979). The contemporary philosophy of science, however, would claim that it is an illusion to believe that science can be reduced to a simple, *objective*, and entirely rule-bound methodology. Thomas Kuhn argued that such opinions are based on science textbooks that fail to tell the truth about the history of science (Kuhn, 1996). In contrast to academic psychology, psychiatry has retained a more heterogeneous – even if contradictory – theoretical background. The main question at the start of the twenty-first century is whether psychology and psychiatry can only be governed by certain particular scientific methodologies or if it is possible to accept the existence of different approaches to acquire knowledge. Paul Feyerabend pointed out that "the idea that science can, and should, be run according to fixed and universal rules, is both unrealistic and pernicious" (Feyerabend, 1980). In actual fact, therapeutic practitioners find it unsatisfactory to consider introspective experience and objective behavior as mutually exclusive, as if they were distant continents with no contact between them. Modern therapeutic theories are thus becoming increasingly eclectic, and the gulf that used to exist between introspective psychoanalysis and behavior therapy, for example, is in the process of disappearing.

Self and Identity

Philosophical concepts of 'self' have led to psychological consideration of the nature of 'identity.' Disturbances of the inner equilibrium of the components of the self, which shape identity, are brought about by processes of remembering, making clear the potential for explanation inherent in a theory of identity formation based on a psychology of the self. As Lévinas in particular has shown this cannot be restricted to a theory of the structure of the 'self' (Lévinas, 1987); rather it must take account of interpersonality; the existence of others (the 'trace of the other'). Any attempt to describe the danger to processes of identity formation posed by the existence of the other from the perspective of the psychology of the self must take account of the 'ontology of the in-between' already developed by Martin Buber (1994). For, as Theunissen (1965) demonstrates in his major work on intersubjectivity, taking the other seriously in its own being involves transcending the intentionality mode.

This philosophical/psychological concept is based on the assumption that components of a person's self can manifest themselves in others and can exist further in them.

The basis of this primary interpersonal constitution of the psyche is the mother–child dyad of early childhood. In a way, people unconsciously always retain parts of their childhood dyad 'within them,' although they nevertheless consider themselves to be ego-centered 'individuals.' In a system of ideas in which the *cogito* is identified with the empirical ego, the 'interpersonal self' cannot be conceived. This primary (but extremely repressed or internally never realized) interpersonal constitution of the self has consequences for how people deal with the familiar and unfamiliar, both in the other and within themselves, where aggression is concerned. Christian Scharfetter, referring to Graumann's theory of subjective perspectivity, rightly refers to the fact that precisely the most intimate personal area of a person, his own unconscious, constitutes an alien entity, an unfamiliar area of sinister mystery. Scharfetter (1994) puts this as follows: "The other is not simply an alien entity, however." The other may very well be familiar; it can be close, it can be experienced as analogous (not homologous). Indeed, the alien is able to strengthen and reinforce the self. It is through the 'You' that the 'I' recognizes itself. This is an important factor where psychotherapy is concerned. However, confrontation with the alien within the self is painful; it requires not only cognitive efforts (Hegel's 'strenuous toil of conceptual reflection'), but also psychological effort in the form of crises in identity development.

An extremely effective defense mechanism here is that of 'projective identification.' This means that the unknown within the subject is discovered in others by projection and combated there. Streeck-Fischer says, for example, that 'the confrontation with the alien has become a shock experience, one which hampers successful interaction with the alien. The alien is threatened as a means of stabilizing one's own threatened self' (Streek-Fischer, 1994). As Streeck-Fischer shows, this mechanism becomes particularly effective when one's own position is not only under pressure from the danger posed by crises in the formation of identity but is also reinforced by social pressure. Social devaluation of specific features of the self can significantly increase projective identification in the sense of the development of aggression. Hans-Joachim Maaz, for example, shows how in East Germany "social constraints under a repressive authoritarian system led to the self becoming alien and the alien becoming one's own." Maaz describes the resulting aggression as follows (Maaz, 1994): "violence and hatred of other people are always evidence of internal tensions within someone, of his no longer being able to find and develop the self and the essential but of having to live a life too much of which is imposed by others."

One of the great figures in the theory of *mimesis* is René Girard. In various works, notably *La violence et le sacre*, Girard developed a theory of mimetic occurrences (Girard, 1977). If one accepts his thinking, the main point of the Oedipal drama, which in Freudian theory is said to mold early childhood, is not the Oedipal aspect as such – the desire for the mother in the Freudian sense – but the mimetic rivalry with the father. In an early work of 1961, *Mensonge romantique et vérité romanesque*, Girard elaborated on a discovery central to the entire development of his theory. He was able to identify a phenomenon of 'mimetic desire' in nineteenth- and twentieth-century novels from Stendahl to Flaubert and Proust. The novels he examined shared a peculiar basic structure: the main characters desire someone else, but their feelings are directed toward a third person, a '*mediateur*.' Analyzing Stendhal, Girard says: "in most cases of Stendhalian desire, the *mediateur* himself desires the object, or could desire it. This desire, whether real or assumed,

is precisely what makes the object infinitely desirable in the eyes of the subject."

Desires, needs, and yearnings are thus described as being something not genuinely given, something brought forth internally by drives or makeup, but are 'read,' taken on from a third party because of mimetic dependency. The basic events in the process of identification can thus be described as follows: if we can understand the other in a recreative sense only by putting ourselves into the other's intentions, into that person's world of desires, this means that we have to identify with that other. The amazing consequence of this is that processes of identification are necessary for a proper interpretation of reality. In this sense, one can say that a rational explanation of the world is possible only if there is a fundamental willingness to identify with others.

As a result, one can argue that in psychiatric patients this rational world access is hampered by their impaired interpersonal relations, that is, due to disturbed mimetic processes (Emrich, 1995).

Modern Use of Philosophy in Psychiatry

Fulford, Stanghellini, and Broome suggest five key ways in which philosophy can aid practice in mental health care (2004), which should be considered by all who work in the field – patient-centered care, supporting new methods of service delivery, advancing research in neuroscience, psychiatric training and supporting an 'open,' international society of psychiatrists.

The concept of patient-centered care focuses on the patient and their family to elicit their personal values before involving the wider team and applying specific clinical skills (Fulford, 2004). This could help facilitate engagement and thus improve clinical outcomes. Where values conflict, the authors suggest seeking the advice of the multidisciplinary team before building an awareness of the situation, applying reasoning skills, obtaining knowledge relevant to the decision – including from relevant research – and using communication skills appropriately to reduce and resolve conflicts (Fulford et al., 2004).

The challenges of the general, world-wide move toward multidisciplinary team working in mental health can also be framed from a philosophical point of view. In theory, this allows a variety of professionals who have different training programs, skill sets, and priorities to meet and discuss patient care pathways. On the other, this team work has been criticized for allowing some patients to fall 'through the net' through lack of collaborative decision-making (Onyett, 2003) and many some have suggested that this may be due to the challenge to the doctor's traditional responsibilities for patient care that come from other professional groups (King, 1991). Columbo and colleagues suggest that differences in team member approaches may be framed by unrecognized differences in models of pathology (2003). Fulford, Stanghellini, and Broome suggest that this very conclusion leads to a more complete analysis of the situation, using J. Austin's theory around 'clear thinking' to assert this contribution of philosophy to psychiatry (2004). They suggest that acknowledgment of the different phenomenology is already being utilized to drive service improvements, with examples including Bracken's novel approach to managing post-traumatic stress disorder in traditional societies (2002) and Sabat's use of conversational analysis to improve communication with those who suffer from Alzheimer's dementia (2001).

The development of neuroscience and neuroimaging technology over the past few decades has presented novel challenges to the traditional phenomenological approaches. In particular, research can present new information to contribute to the information on the interplay between genetic, environmental, and psychological factors in leading to mental illness, which can challenge traditional knowledge and definitions.

Andreasen predicted that neuroscience would bring these issues, including issues around self and personal identity, to the fore (1991). The research in this area is evolving rapidly, on both a condition and phenomenological basis – posing challenges to psychiatry and philosophy.

Training for psychiatrists and ideally other health professionals is focused around encouraging exactly the kind of independent thought and contribution valued by the Greek fathers of philosophy and discussed in an earlier part of this article. The concepts central to conflict resolution and communication are a core part of the curricula for health professionals, particularly doctors. Concepts of ethics, including a basis in Greek philosophy, are a key component of undergraduate medical curricula for doctors in training (e.g., Stirrat et al., 2010) and postgraduate practice (World Psychiatric Association, 2011).

The final main contribution of philosophy to psychiatry noted by Fulford, Stanghellini, and Broome is in ensuring that psychiatrists and other professionals are part of an international community that seeks to be supportive and protective of patients (2004). The contributions to psychiatric practice of politics, scholarship, historical context, individual values, professional and institutional standards (Matthews, 2005; Robinson and Walter, 2013) make psychiatry unique among medical disciplines. Episodes where psychiatrists contributed to the widespread euthanasia of those from unfavorable groups in Nazi Germany (Robinson and Walter, 2013) and labeling of political nonconformists as 'schizophrenic' in the USSR (Bloch and Reddaway, 1977) show the vulnerability of psychiatry arising from a failure to maintain a balance of different perspectives and pursuing what Locke described as 'enthusiasms' (Fulford et al., 2004). Maintaining an 'open society' will ensure that a shared discipline, analysis, respect for individual cultures and methodological pluralism protect against future 'enthusiasms' on an international and national level (Birley, 2000). The World Psychiatric Association, European Psychiatric Association, and events such as the United Kingdom Royal College of Psychiatrists annual International Congress are central to the international collaboration, which Birley suggests is essential to safeguard the good standing of the profession in society into the future.

Phobias Across the Lifespan

Abstract

Marked and persistent fear cued by specific objects or situations accompanied by the compelling desire to escape from or avoid the encounter with such objects or events are the key features of specific phobias. Depending on the type of situation that is feared or avoided, specific phobias are further subdivided into five different specifiers: (1) animal; (2) natural environment; (3) blood, injection, or injury; (4) situational; and (5) other subtypes. Specific phobias are frequent in the population and vary across life span. For adults, prevalence rates vary between 11.3% for lifetime and 8.8% for 12-month periods. For children and adolescents, prevalence rates are slightly lower. Females are affected more often than males. The nature of phobic fear varies with the proximity of the phobic object, showing a close interaction between cognitive and emotional systems in the brain. While the anticipation of a phobic object in a certain context is associated with general hypervigilance, selective attention and freezing are engaged once the phobic object is detected. When the phobic object approaches, autonomic arousal increases and the organism prepares for escape. The neural networks organizing these defensive behaviors can be activated by innate threats as well as by learned associations acquired either by direct experience or by observation and communication of other people or even media. Specific phobias can be effectively treated using single-session exposure. During exposure, session patients are confronted with their feared situations and objects in reality and remain in this situation until the fear response subsides. Such exposure treatment is highly effective with effect sizes varying between $d = 1.41$ and 3.80, depending of the primary outcome measure used. Exposure therapy is particularly effective for treating avoidance behavior.

Defining Specific Phobias

Marked and persistent (for 6 months or more) fear cued by specific objects or situations accompanied by a compelling desire to escape from or to avoid such objects or situations – if possible – are the main diagnostic criteria for specific phobia (criterion A and C in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (*DSM-5*); American Psychiatric Association (APA), 2013). Moreover, the fear response is almost always evoked by the phobic object (criterion B in the *DSM-5*; APA, 2013) and increases in intensity with increasing proximity of the external threat (e.g., with the time of entrapment and reduction of oxygen supply, the distance to the spider, and so on) and fades immediately when the situational threat disappears (e.g., the door is opened or the spider is caught and put outside). Thus, the cued nature of the fear is an important defining feature for specific phobias. To meet the criterion for a mental disorder, the fear has to be out of proportion to the actual danger posed by the object and to the sociocultural context (criterion D), and the fear or avoidance has to cause significant distress or impairment in social, occupational, or other important areas of functioning (criterion F). This last so-called impairment criterion is probably the most problematic of all *DSM-5* criteria for specific phobia (see Emmelkamp and Wittchen, 2009). One central issue with regard to the impairment criterion is the question of comorbidity. Several epidemiological studies show very high comorbidity between different anxiety disorders, including specific phobias (see Wittchen et al., 2003). In a sample of more than 1000 anxiety patients, Brown et al. (2001) observed that 70% of patients with a specific phobia diagnosis had a comorbid anxiety or mood disorder. The comorbidity rate, however, dropped to 33% among a subset of patients for whom specific phobia was the principal diagnosis. In other words, whether or not the specific phobia is the principal (i.e., the most severe) disorder strongly predicts the level of functional impairment. Moreover, data from the Early Development Stages of Psychopathology (EDSP) sample suggest that comorbidity increases steadily with increasing duration of the specific phobia (see Bittner et al., 2004). Data from the National Comorbidity Survey Adolescent Supplement (NCS-A) show that 19.3% of all adolescents (ages 13 to 18 years) report a lifetime prevalence of specific phobia, but only 0.6% of all adolescents reported 'a lot' or extreme impairment and severe or very severe distress (Merikangas et al., 2010), suggesting that treatment is needed only for a minority of individuals. Given that increased comorbidity often is associated with stronger functional impairment, however, the requirement of meeting the impairment criterion for specific phobia might foreclose early access to effective treatments when the disorder has not become chronic and is still a pure disorder. This is particularly important because effective treatments are available particularly if the specific phobia is still at an early stage and relatively isolated (Davis et al., 2012). In principle, the criteria for the diagnosis of specific phobias do not differ for adults and children except that children express their marked fear more nonverbally by defensive behavior like clinging, crying, tantrums, or freezing.

Diagnostic Features of Specific Phobias

Because one of the key features of specific phobias is the close link of the fear responses to the eliciting situations, it may not come as a complete surprise that, traditionally, phobic disorders have been categorized according to the feared objects and situations, translated into Greek or Latin preceding the word phobia. Although attractive for the public media who love to call on Friday the 13th to ask phobia experts about patients who suffer from *paraskevidekatriaphobia*, such endless lists of

phobias are scientifically and clinically useless. As a consequence, *DSM-5* has confined the subdivision of specific phobias to five specifiers: (1) animal (fear cued by spiders, snakes, insects, mice, dogs); (2) natural environment (fear cued by heights, thunderstorms, being on or in the water); (3) blood, injection, or injury (fear cued by seeing blood, receiving injections or transfusions, or fear of other medical care, including dental care); (4) situational (fear cued by entrapment in enclosed places like elevators, tunnels, airplanes, buses); and (5) other (fear cued by other stimuli, like choking or vomiting). Although gender distribution, age of onset, and treatment response are similar for these subtypes of specific phobias (LeBeau et al., 2010), the physiological pattern of the fear response, as well as the level of impairment and comorbidity, differs between the subgroups of specific phobia. Specific animal-type phobia is characterized by a sympathetically dominated autonomic physiological fear response pattern preparing the organism for escape (see Hamm et al., 1997; Globisch et al., 1999) accompanied by the central concern of freaking out and loosing control (see Lipsitz et al., 2002). Specific blood-, injection-, or injury-type phobia is marked by a diphasic fear response, an initially sympathetically mediated increase in heart rate and blood pressure followed by a vagally mediated bradycardia and hypotension, which ultimately may lead to a syncope preparing for tonic immobility (Friedman et al., 1993; Hamm et al., 1997), accompanied by the concern of fainting or feel nausea. Specific situational-type phobias (e.g., being entrapped) are characterized by strong cognitive symptoms and concerns like losing control, going crazy, or suffocate accompanied by a very strong urge to escape (e.g., from the enclosed place). Finally, specific natural environment–type phobias are characterized by symptom reports of dizziness (in case of fear of heights) and strong avoidance dispositions that often are accompanied by the central concerns about the potential danger of the situation (the tornado might hit our house; the lightening might set our house in fire). These different subgroups of phobias correspond closely to the clusters of situations that are most feared by children, at least when these fears are assessed with open-ended questions. Asking 394 children between 7 and 12 years old, "What do you fear most?" Muris et al. (1997) found that 10.2% of the entire sample reported fear of spiders as their most intense fear. Besides the fear of animals (fear of snakes was also among the top 10), children reported fears from the natural environment cluster (e.g., darkness) as well as blood- and injury-related fears (e.g., illness), and fear of suffocation (e.g., not being able to breathe) belonging to the cluster coded as situational fears. The prevalence of common fears varies across the life span. During early childhood, intense sensory stimulation often evokes a strong fear response in newborns up to the age of 6 months. Actually, the intense sound produced by striking a steel bar with a hammer was used as the unconditioned stimulus to evoke unconditioned fear in the famous case of Little Albert (Watson and Rayner, 1920). Fear of strangers (including costumed characters, particularly if they produce startling loud sounds) and separation from attachment figures are prominent during the first year of life. Preschoolers often fear ghosts, potential burglars, and monsters from movies, particularly during the night when it is dark. Later (between 5 and 7 years), these fears of annihilation shift to more realistic fears of thunderstorms, disasters, death, and war and also the fear of potentially threatening animals (like snakes, spiders, or dogs) (Muris et al., 2003). In the ages between 8 and 11 years old, children often report fear of poor performance in the academic domain but also in the area of athletic performance (McDonald, 2001). In addition, fear of medical procedures is common during this age. Later, during adolescence, fears of being rejected, being negatively evaluated by other adolescents, or acting in an embarrassing way become prominent. The onset of the different types of specific phobias often can be traced back to these vulnerable phases during the ontogenetic development (Öst, 1987a).

Prevalence of Specific Phobias

Prevalence of specific phobias is high and varies across the life span. According to the results of the National Comorbidity Survey, prevalence estimates for specific phobias in adults vary between 11.3% for lifetime and 8.8% for 12-month periods (Kessler et al., 1994). In adolescents, prevalence rates are higher (19.3% according to the NCS-A; Merikangas et al., 2010) but considerably lower if only specific phobias with strong levels of distress and impairment are included. Data from the EDSP study – a longitudinal study – report prevalence rates for specific phobias of 10.9% (12-month period) for adolescents (age range from 14 to 17 years; Beesdo et al., 2009). For children, prevalence rates are lower and vary between 2.6 and 9.1% with an average of 5% across studies (Ollendick et al., 1997). In the elderly, the prevalence of specific phobias decline. Estimates range from 3.1% up to 7.5% in the NCS (Kessler et al., 2005). The larger estimates in the NCS may be due to the inclusion of diagnoses that have remitted (Wolitzky-Taylor et al., 2010). Females are affected more often than males, at rate of approximately 2:1.

Etiology: Understanding Specific Phobias from a Neuroscience Perspective

According to recent neuroscience-based models, emotions like fear can be conceived as action dispositions associated with efforts to escape or avoid danger or pain (Lang and Bradley, 2010) and are rooted in the survival circuits of the brain (see LeDoux, 2012). These defense circuits of the brain feed back to the sensory systems facilitating the detection of threatening and potentially harmful stimuli and prompting defensive reflexive, autonomic, and motor responses to counter threats. Animal and human data suggest that such defensive behavior is organized dynamically in several stages depending on the physical distance (*proximity*) of the threat (i.e., the phobic object), as outlined in the *threat imminence model* by Fanselow (1994) (see also Adolphs, 2013; Blanchard, 1997; Lang et al., 1997). At the first stage, when the organism is in a context in which a threat (e.g., a phobic object) has been encountered previously, but has not yet been detected (preencounter defense), preemptive behavior including threat-nonspecific

vigilance is engaged. Once the threat is identified (post encounter), the organism freezes and increased selective attention is allocated to the potential threat. Circa-strike defense, characterized by strong autonomic arousal and escape behavior, is activated when the threat is imminent. In a recent experiment, we tested this model by measuring electrical brain responses during the presentation of spider pictures to individuals with spider phobia and control participants (Michalowski et al., 2009). The main results of this study together with a sketch of the model can be seen in **Figure 1**.

Informing individuals with spider phobia that a phobic object (picture of a spider) might occur in the current (experimental) context puts the phobic individual (not the control group) in a state of general hypervigilance toward all visual stimuli that occur in such environment, irrespective of their emotional content – phobic individuals responded with larger P1 amplitudes (peaking 100 ms after the onset of the picture) of the visual evoked potentials over the occipital cortex to both neutral and spider stimuli (see right panel (a) of **Figure 1**). Later (300 ms after stimulus onset), phobic individuals show a larger P3 to the spider pictures relative to controls over the parietal cortex, and this group difference did not occur for the other emotional contents (which were significant for both groups), suggesting that selective attention to spider pictures was enhanced for phobics. Such a dynamic view of defensive reactivity integrates cognitive and emotional processes involved in the expression of phobic fear. If the phobic stimulus is more distant, the organism freezes, selective attention is increased together with increased activation of the amygdala (Etkin and Wager, 2007 for a meta-analysis) and is associated with a potentiation of protective reflexes like the startle response (Hamm et al., 1997). During circa strike, when the feared cue is proximal, autonomic arousal increases and selective attention to external sensory signals are reduced to optimize the escape response. In a recent study, we manipulated the proximity of a stress by increasing the size of the visual picture predicting the occurrence of a painful event. The participants had the opportunity to escape from this painful stimulus by pressing a button as soon as possible. When the anticipated threat was more distal, startle responses were potentiated and the brain responses evoked by the startle probes also were augmented, suggesting that participants were in a freezing mode. When finally arriving at the 'circa-strike zone,' autonomic arousal strongly increased and was associated with an inhibition of the startle responses (Löw and Hamm, submitted for publication). Interestingly, the P3 amplitude to the startle probe decreased dramatically, supporting the view that all attention channels are shut down

Figure 1 Left panel: The threat imminence model: Defensive behavior in mammals is organized as a cascade of three different stages. Right panel: Brain responses (evoked potentials) to spider and mushroom pictures in spider phobics and healthy controls. (a) Spider-phobic individuals show larger P1 amplitudes over the occipital lobe both to spider pictures (right) and to neutral pictures suggesting a general hypervigilance to all visual cues when phobic individuals are informed that spider pictures might occur. (b) After 300 ms, spider-phobic individuals show larger amplitudes to spider pictures than controls (attention bias) over the parietal cortex, and no group differences were found for neutral stimuli. During postencounter, phobic pictures selectively catch more attention in phobic individuals.

prior to escape. Recent human functional magnetic resonance imaging (fMRI) data also support this interpretation. Using an artificial intelligence predator model to study the dynamics of defensive behavior in humans, Mobbs et al. (2007, 2009) found that postencounter defense activated the amygdala and the subgenual anterior cingulate (ACC), whereas circa strike (when the threat became more imminent) engaged the periaqueductal gray (PAG) and the dorsal ACC, which also is involved in analgesia (Petrovic et al., 2002). From a learning perspective, imminent unconditioned threats (odors from predators, loud noises, pain, lack of oxygen supply) are transmitted from the sensory systems via the amygdala to the hypothalamus, which connects to the dorsal PAG that directs the expression of escape behavior (see LeDoux, 2012). Thus, unconditioned proximal threat activates innate defensive behaviors. More distant threats (e.g., conditioned stimuli that predict the potential occurrence of an innate stress or distant phobic objects) are associated with increased vigilance and freezing behavior. This information also is transmitted via sensory systems to the lateral amygdala and from there via intra-amygdala connections to the central nucleus of the amygdala, which is connected to the ventrolateral PAG (Maren, 2001; Fanselow and Poulus, 2005). With this dynamic model in mind, the vital question remains, how does a specific cue acquire the properties of a phobic object?

According to the model proposed by Rachman (1991), cues can become phobic objects by three different learning experiences: (1) Phobias can be acquired by *direct associative learning experiences* (e.g., if somebody was attacked by a dog). Indeed, numerous fear-conditioning studies show that a previously neutral cue that has been associated with a painful stimulus reliably leads to freezing, potentiation of the startle (Hamm and Weike, 2005, for review), and activation of the amygdala (Etkin and Wager, 2007) after this learning experience. (2) These networks are activated not only during direct conditioning experience but also through *social observation* with no personal experience of the aversive event (e.g., pain). In a study from Olsson et al. (2007), participants observed a movie displaying a male participant receiving painful stimuli in a fear-conditioning experiment. Presenting the fear-conditioned stimuli to the observer (who never received any unconditioned stimulus) also resulted in a clear activation of the amygdala. These data clearly indicate that observational learning relies on the same mechanisms as those involved in learning fear through direct experience. Thus, phobias can be acquired not only by direct aversive experience but also by observing what others have feared before, a phenomenon that has been demonstrated convincingly for the acquisition of snake phobia in primates by Mineka and colleagues (Mineka and Cook, 1993). (3) Fear also can be acquired by *symbolic communication*. Instructing individuals that an aversive event (e.g., a painful stimulus) might follow a certain stimulus (e.g., a blue square) results in robust fear responses to that stimulus (see Grillon et al., 1991). Not surprisingly, the same neural network including the amygdala and the insular cortex is activated during such instructed fear (Phelps et al., 2001) as during direct fear conditioning. These findings clearly demonstrate that specific phobias can be acquired either by (1) direct experience, (2) observing an intense fear response in others, and (3) communicating that some objects or situations might be dangerous. These different learning experiences are mediated by the same neural network including the amygdala and the insula both being core elements of the fear network. Moreover, genetic predisposition seems to modulate how such learning experiences affect the neural network in the brain. Finally, epidemiological evidence from the Dunedin longitudinal study suggests not only that only aversive learning experiences may shape the fear circuit in the brain but also that early exposure to potentially fearful situations might help to immunize the fear networks in the brain. Examining the origin of fear of heights, Poulton and Menzies (2002) found that individuals at age 11 or 18 years with height phobia did not experience serious falls during childhood but rather had less exposure to height stimuli early in life. These findings clearly demonstrate not only that learning experiences are relevant for the development of phobic fears but also that early learning experiences of fear reduction after exposure might help to prevent fear dispositions during childhood from being transferred to phobias that are present during adulthood. Studies asking patients with specific phobias retrospectively about the origins of their phobia using the *Phobic Origins Questionnaire* also find these four pathways. **Table 1** presents the percentage of the answers about the triggers of their phobia for the different types of specific phobias.

Treatment of Specific Phobias

Exposure-Based Treatments

Specific phobias are particularly responsive to exposure-based therapies and therefore are considered the treatment of choice for this disorder (Hood and Antony, 2012). In a meta-analysis, Wolitzky-Taylor et al. (2008) conducted a literature search for treatment studies published between 1966 and 2007 and extracted 33 studies that fulfilled the criteria of using (1) a randomized clinical trial (RCT) with (2) patients meeting full *DSM* criteria and (3) reported phobia-specific

Table 1 Percentage of patients with specific phobias according to the retrospectively recalled origin of their phobia

Origin of phobia	*Animal type*	*Blood/injection injury type*	*Situational type*	*Natural environment type*
Direct conditioning	56%	51%	69%	12%
Vicarious learning	41%	18%	9%	16%
Learning by information	23%	5%	10%	4%
Fear was always there			39%	

The percentages presented in this table are based on results from the following studies: Öst (1987b); Merckelbach et al. (1992); Sartory et al. (1992); Kleinknecht (1994); Menzies and Clarke (1995). The sum of the percentages does not always add up to 100 because multiple answers were allowed in some studies.

outcome measures. Meeting these criteria, there were overall 1193 patients receiving 90 treatments administered. Similarly Choy et al. (2007) did a literature search for treatment studies published between 1960 and 2005 and selected 31 studies that (1) included at least two groups (without the criterion of being an RCT), (2) investigated clinically diagnosed phobia patients (excluding all studies with analogue samples), and (3) reported behavioral or self-report outcome measures. Although using comparable Internet search engines, there was little correspondence (only seven studies were listed in both reviews) between the studies selected for both reviews, thus adding an additional 1527 treated patients to the overall sample. The conclusions drawn from both the meta-analysis and the narrative reviews are clear: Exposure-based therapies result in significantly better outcome at post-treatment irrespective of whether assessed by verbal report measures or by behavioral avoidance tests (BAT) relative to the wait-list control condition (Choy et al., 2007; Wolitzky-Taylor et al., 2008). The overall effect size for this comparison is $d = 1.05$ and is comparable for behavioral measures and questionnaire data. In the group of patients with a specific animal-type phobia, 92% of the patients treated with *in vivo* exposure compared with 0% of the wait-list control were able to perform the terminal task in the BAT (Bandura et al., 1969; Williams et al., 1984). Comparable percentages were reported for patients with either height or driving phobia (87% of the treated patients completed the terminal task of the BAT) and claustrophobia (79% completers; Öst et al., 2001). Choy et al. (2007) found 16 studies in their review, which investigated outcome measures in a follow-up period, ranging from 6 to 14 months and found stable treatment effects for the treatment of animal phobia, height phobia, flight phobia, and claustrophobia. Some studies even found an increase in the treatment effects, whereas other studies did not find any further improvement compared with postmeasures.

Exposure Techniques

Exposure to the feared situation can be performed *in sensu* – that is, the patient is instructed to imagine to be in the feared situation, and often, the intensity of the fearful environment is increased step by step using a technique named 'systematic desensitization' and developed by Wolpe (1958). Wolpe (1958) had suggested that *conditioned inhibition* would be the crucial mechanism for the curative effect of systematic desensitization – for example, if a relaxation response that is antagonistic to the fear response is elicited during the feared cue, it consequently will reduce the fear response so that the fear cue itself will become a conditioned inhibitor (*counter-conditioning*). Numerous studies in the 1960s, however, clearly showed that the induction of relaxation is not a necessary condition for effective exposure treatment (for a critical review, see Tryon, 2005). As a consequence of these developments, systematic desensitization has fallen out of favor and behavior therapy of specific phobias has shifted to exposure *in vivo*, in which patients are confronted with their feared situations or objects in reality (e.g., patients are encouraged to approach and touch the feared animal until the fear subsides, Hellström and Öst, 1995), or patients climb the highest building in the area together with the therapist and practice standing at the top without touching the railings (Williams et al., 1985), or they are entrapped in a narrow dark chamber until the claustrophobic fear subsides (Öst et al., 1982). Such exposure *in vivo* very effectively has been done in one session as described by Öst (1985, 1987b, 1989) for the treatment of animal-type and blood- or injury-type phobias and by Emmelkamp and Felten (1985) for fear of heights. One-session treatment includes the active participation of the therapist in activities, such as explaining the treatment rational, modeling, and collaborating with the patient during the single-session active exposure. The entire therapy session is videotaped, and in some cases, patients are invited to return to the clinic to watch parts of the video 1 or 2 weeks after the exposure session. The active treatment session is preceded by a careful behavioral assessment, including the etiology of the phobia (e.g., conditioning experience), avoidance and escape response patterns, and a detailed analysis of the central concerns and the feared consequences of the exposure (e.g., I might not get enough oxygen when trapped in this chamber). The exposure session is divided into several behavioral exercises that are arranged in hierarchical steps. The patient makes a commitment to remain in the exposure situation until the fear fades away and not to escape from the situation during the treatment. Before moving to the next step, the therapist describes that task, demonstrates how the patient is expected to interact with the feared object, and then has the patient carry out the interaction with the object or situation by himself or herself. Before but also during each behavioral exercise, the therapist prompts the patient for his central concerns and feared consequences to explicitly challenge them during the exposure. The patient is instructed to interact with the feared object or situation at each behavioral step until the fear dissipates. The entire session ends when the final approach goal is met, and the level of fear has been reduced to 50% of its highest value or, ideally, has vanished. On the basis of a thorough review of 25 controlled treatment studies of specific phobias (with 800 patients and 150 control subjects), including many conducted at his own institution, Öst (1997) concluded that one-session *in vivo* exposure is the treatment of choice for specific phobias. Across different types of phobias, such individual single-session treatment results in a clinically significant improvement (e.g., an improvement of two standard deviations relative to the mean symptom score of the patient population) in 77–95% of patients. Also noteworthy is that the average duration of such treatment varies between 1.9 and 3.5 h. One-session treatment of specific phobia has been evaluated empirically for spider phobia, blood and injection phobia, and claustrophobia (see review by Zlomke and Davis, 2008). Significant effect sizes were reported for self-report measures of fear (as assessed by several questionnaires, mean $d = 1.98$; range 0.91–3.05) and reported distress during standardized behavioral avoidance tests (mean $d = 2.20$; range 0.79–3.80). Comparable effect sizes ($d = 1.41$) were reported by Öst et al. (1997) for a 3 h one-session treatment of 14 patients with flight phobia during which the therapist accompanied each patient during the 30 min bus ride to Arlanda airport, during the process of checking and boarding, and during the flight from Stockholm to a domestic destination (overall, 90 min), as well as during the entire procedure on the

return flight to Stockholm. Fear of flying was reduced significantly after this single-session treatment, and 93% of the patients (13 out of 14) took an unaccompanied return flight on their own after treatment. More recently, Haukebo et al. (2008) reported significant improvements in a group of 10 patients with dental phobia after a one-session exposure treatment by a dentist who was trained specifically in this method by Öst.

Exposure in Virtual Reality

With increasing availability of virtual reality (VR) technology, it is now possible to use computer-generated interactive VRs, including visual displays of moving objects, other sensory inputs, and body-tracking devices to conduct exposure therapy. Patients visit these VRs for a prolonged period of times during several sessions. Virtual reality exposure therapy (VRET) is particularly helpful when it is difficult to recreate an environment for exposure in reality. Therefore, in the case of treating specific phobias, VRET has been empirically evaluated primarily for treating flight and height phobia. In their meta-analysis of VRET for anxiety disorders, Powers and Emmelkamp (2008) found 11 studies that tested clinical effectiveness of VRET for treating specific phobias (eight studies investigated treatment effects in flight phobia and four studies investigated treatment effects in height phobia using VRET). Studies that compared VRET either with a wait-list control group or with groups receiving nonspecific interventions, such as relaxation or attention control training in an RCT, found VRET to be more effective than nonspecific interventions. Overall effect sizes were in the range of medium to large across all measures, including verbal report of general distress, cognitive measures, avoidance behavior, and autonomic responding (see Powers and Emmelkamp, 2008; Meyerbröker and Emmelkamp, 2010 for reviews; see also the article on virtual reality in this volume). In the case of height phobia, VRET is as effective as *in vivo* treatment (Emmelkamp et al., 2002). In case of flying phobia, however, results are more mixed. Two studies compared VR with *in vivo* exposure for flight phobia and found VR to be equally effective irrespective of whether verbal report measures or behavioral tests (taking a graduation flight) were taken as outcome measures (Emmelkamp et al., 2002; Rothbaum et al., 2002), particularly at follow-up assessment (see Wolitzky-Taylor et al., 2008). Data of Mühlberger et al. (2006), however, suggest that including *in vivo* exposure (e.g., taking a graduation flight) increases the long-term effects of exposure therapy in VR. Completion of the graduation flight was a strong predictor for long-term treatment efficacy (Mühlberger et al., 2006). Thus, it is still an open question whether VRET of flight phobia is as successful as the 2-day program presented by Van Gerwen and colleagues, showing that 98.6% of 685 treated patients did fly within the next 12 months (Van Gerwen et al., 2002). Santos and coworkers recently reported comparable success rates (Santos et al., 2011).

Summary

Marked and persistent fear cued by specific objects or situations accompanied by a compelling desire to escape from or to avoid such objects or situations – if possible – are the main diagnostic criteria for specific phobia. Although exaggerated fear responses can be elicited in principal by almost each imaginable object (e.g., trypophobia, fear of holes), current diagnostic systems (*DSM-5*) code discriminate specific phobias based on the phobic stimulus into five different specifiers. Specific phobias are quite common and vary across the life span with about 20% prevalence rates in adolescents, 11% in adults, and about 5% in the elderly. Much progress has been made in the recent decades in understanding the neural networks involved during encoding of the phobic stimulus and orchestrating the fear response. The lateral amygdala seems to be a core structure involved in the detection of the emotional significance of and transferring this information to the ACC and the anterior insula. The central nucleus seems to be involved in the organization of the defensive behavior that follows a dynamic pattern from freezing to escape depending on the proximity of the phobic object. Neutral situations or objects can acquire phobic quality and, thus, get access to these networks via direct aversive learning experiences, by observation of others making such experiences, or by the information that some situation might be dangerous. The most effective treatments of specific phobias are exposure-based therapies that can be administered effectively even in a single session.

Abstract

This article outlines 200 years of neurolinguistic investigations into the nature and causes of phonological disorders in human language. Early empiricist principles such as association frequency, force/strength, and activation/inhibition, forged theoretical relationships among sound types (phonemes), words, and word meanings that drove the understanding of normal and disordered phonology from antiquity through the mid-twentieth century. Throughout this period, researchers in natural philosophy as it evolved into psychology understood sound errors as substitutions of elements sequencing errors within the strictly concatenated links between sound neighbors in the familiar associative sound chains that comprised the phonological forms of words in the British empiricist such as John Locke. Near the turn of the nineteenth century, however, neurologists such as John Hughlings-Jackson and Sigmund Freud challenged associationism, arguing for a more abstract, sensory conceptualization of sounds. Errors, including slips-of-the-tongue, were noted to occur over wider expanses of sound than those permitted by the associationist models. This was a watershed time period in the history of phonology, and it was during the late-nineteenth century that the concept of the phoneme was crafted from within phonetic science. To this was added a deeper phonology from the Prague School, followed upon by the work of Roman Jakobson. By the mid-twentieth century, the cognitive sciences were giving rise to a variety of influential mental models for language processing, including nonassociationist serial modeling as well as later hierarchical, top-down serial models such as the one crafted by Merrill Garrett and later by the nonserial, computer interactive activation model of Gary Dell and colleagues such as Nadine Martin. Today's computer simulations of normal and disordered phonological systems, together with advances in '*in vivo*' neuroimaging technologies, allow a more profound understanding of the real-time contributions of the 'neuro' and the 'linguistic' in understanding phonology. As we can now predict errors in simulated systems and predict patterns of recovery in individuals with aphasia, it is quite clear that as science advances, so does the characterization of phonological disorders.

Introduction

In Buckingham and Christman (2008), we outlined disorders of both phonetics and phonology, almost as if the two levels could be easily dissociated; they cannot. In the present article, we will be sensitive to some sort of interface between the two for the sake of much linguistic and psycholinguistic modeling that keeps them apart.

We will also assume that 'phonological disorders' go as phonology is characterized at the time at the point in history of their description. We will claim that throughout the history of considering 'phonological disorders,' we must consider what phonology could have been taken to be. As a consequence, we will frame our article in terms of the continuity and change of 'phonology,' and how 'the models make the man,' from Jacques Lordat to the connectionism of Dell's interactive activation (IA) to Goldsmith's harmony seeking model, which works off the Hopfield Nets of Smolensky's physics, although we will have relatively little to say about Hebb, Hopfield, or Smolensky. We are essentially adopting the position outlined by Whitaker (1972, p. 431), where he writes that

> Phonological structure is often studied independently from the other components of language and, until recently, it has been studied in greater detail than these other components for obvious reasons: its accessibility to instrumental measurement and the presumed limitation or finiteness of its scope and content.

In this article, Whitaker demonstrated that importantly as goes the phonological brain, so goes phonology. Our article has a fair amount of material, perhaps worth a new text on *all of this from an historical framework, but we will try to keep the train of ideas as distinct* but intellectually and historically integrated to the extent we can. We hope to go beyond Buckingham and Christman (2008), but our new work must integrate some of the issues touch upon there. Moreover, we will consider some fMRI and DTI studies where appropriate for distinguishing 'the where' of distinct types of phonological disorders that may differ along anatomical/physiological dimensions.

Some Phonological Disorders from Jacques Lordat to Hugo Liepmann

Lordat

Jacques Lordat, among his many other efforts, worked with patients with 'apoplexy' in the latter half of the eighteenth century and the early nineteenth at the Montpellier School of Medicine. By 1843, his collection of cases and analyses resulted in the publication of his 'L'aphasie et l'elaboration de la pensee explicite,' where Lordat constructed essentially a 10-stage production model, which Lecours et al. (1987) and more recently Nespoulous (2013) have characterized as one of the earliest, if not *the* earliest, psycholinguistic model of language production scaffolded off data from aphasia (**Figure 1** French (2013) with English translation (1987)).

We pay special attention to Level 9 where previously concatenated successive sounds are fixed to one another 'securing mechanical harmony' ('solidaire' Fr.) as they pass articulatorily from one to the next. Levels 3 and 4 seem to select words

Figure 1 Jacques Lordat's boxology of speech production (1842–43) redrawn by Jean-Luc Nespoulous. Permission granted. This is a series of steps of language/speech production.

containing prearticulatory 'sounds' and ordering those prearticulatory sounds within the word. Apparently, Lordat did not realize that this was a first ordering to be followed by a second ordering at level 9, as is now recognized in most hierarchical and serial production models.

What we wish to point out here regarding Lordat's model is that the articulatory dynamics of the processes at level 9, intriguingly foreshadow the much later work by Wayne Wickelgren (1969) where the 'sounds' and their left and right contexts of Lordat are 'wickelphones,' and thus they mechanically attach to each other, the left and right contextual (coarticulatory) elements are was an automatic and associative account of the stringing together of what we might call today 'articulemes' or 'gesturemes.'

In summary, Lecours et al. (1987, p. 7) write that

> Lordat (1843) teaches his students that 'from one's decision to communicate one's thought, to the embodiment ("corporification," (Nespoulous, 2013: p. 4 – HWB)) of this thought into conventional sounds, one has to accomplish a succession of various acts, (some of them exclusively mental), each of which should be studied separately.

Naturally, by the time level 9 is being computed, we have traversed the level of ideas to the body. Again, Lordat is prescient in his ability to psycholinguistically intuit and of course here we seen his realization the still enigmatic concept of embodiment. And, although Nespoulous (2013, p. 7) claims that higher level of ordering of prearticulatory segments and *errors* allow us to see without the slightest doubt, "… l'ancetre de la 'paraphasie phonemique," he follows with a few examples of phonemic substitutions which he then claims also look like the slips-of-the-tongue of Fromkin (1973) and other sorts of fluent aphasic phonological distortions that would arise at levels 4/5. Recall, however, that later on we will compare the computations at Lordat's level 9 with Wickelgren's notion of the 'context-sensitive elementary motor response' units – the Wickelphones.

Bouillaud, Auburtin, and Broca

The period leading up from Bouillaud to Broca is a well-charted progression (see Schiller, 1994; LaPointe, 2013 and numerous other works). What mostly comes out of the celebrated Anthropological Society meets during this period are descriptions of patients who had nondysarthric articulatory production disruptions, which, although they actually spoke very little, when they did speak most investigators could perceive that those few articulations were not so easily tagged as 'arthric,' which most of the clinical investigators observed had been secondary to lesions subjacent to the cerebral cortex. Since at that time, and with a glaring neglect of work by earlier neurologists, such as Lordat, there was no description of the actual linguistic levels and elements involved in the speech of the adults with apoplexy and most often right hemiplegia. The terminology was largely restricted to 'sensory' versus 'motor,' or 'arthric' versus that other articulatory feature that was perceived to be more 'fluent' and without what were the signposts of the arthric disorder. Aside from vague notions of 'language,' there were no clear parameters with which to seriously describe what that would entail as far as anything linguistic. Theories had abounded since Bouillaud's (1825) claim that the nonarthric speech disorder was a sort of procedural memory of articulatory construction. Assigning that disorder to the realm of memory allowed the investigators to distinguish it from arthric speech, to assume that it was mediated at the cortex, that it was a product of volition. Assuming that the disorder was a faculty of the cortex, motor explanations were *ipso facto* ruled out, since much before the landmark paper by Fritsch & Hitzig (1870/1960) the cerebral cortex was not considered to control motor movement. Broca (1861) finally pinned that cortical zone to be the inferior portion of the third frontal lobe, Marc Dax notwithstanding, that localization was not necessarily placed within the left hemisphere; that came later (Broca, 1865). This point of all this is that so far, there was no available linguistic model to handle much of any of this, much less any other segmental and lexical disruption at an even deeper psychical/mental/abstract level. So, naturally, there were no true and unambiguous phonological disorders. Rather, up to this point it was primarily to figure out the ontological status of this nonarthric articulation disorder. Indeed, since it was specified as a cortical disorder, it was considered simply to be a 'faculty of articulation,' faculties essentially being the work of the cerebral cortex, under the model of the phrenologists. And, since the phrenologists still held to the

'law of symmetry,' they, too, focused only on the frontal lobe for articulation, but viewed the faculty as a bilateral function.

Karl Wernicke

With Wernicke (1874), what slowly emerges is an anatomical account of a more fluent speech output of patients previously most often assigned to the realm of insanity. They had no signs whatsoever of a patient post apoplexy without a unilateral upper limb paralytic dysfunction and a smooth articulatory output, with neither of the previous noted speech problems. They also ambulated in a normal fashion; few seemed to know they had a stroke; Wernicke, however, did. The patients were quickly rerouted from asylums to stroke units. Wernicke carefully chartered their speech outputs and claimed they are those of normal speakers for the most part. They had semantic word substitutions, and many kinds of sound errors, most of which were substitutions and linear transpositions, some so numerous as to render some supposed target word unrecognizable. These quickly were tagged as 'sensory' aphasic errors, and were not only located far from Broca's area in temporal lobe regions, but were also clearly distinguishable clinically from those nonarthric disorders of Broca; there are now three sorts of segmental output disruptions. From a clinical standpoint (not linguistic yet), it was slowly becoming clear that more 'language-like' errors were being produced by these adults with 'sensory' aphasia. Without the necessary linguistics, Wernicke and other physicians such as Bastian (1869) and Bateman (1890), and even earlier with the work of J. Gesner from 1767 to 1788 (see, Benton (2000) for an analysis of Gesner's work on jargon aphasia) began describing the anomias and other sensory/fluent segmental and lexical errors, which in time would unwittingly open up a clearer idea of just what a phonology might be. However, and very unfortunately, Lordat's model could be of no use; no one knew of Lordat, it seemed. Modern day linguists and naïve historians may very well over interpret what Wernicke was saying in 1874 and may talk of phonological disorders in sensory aphasia. This was not at all the case yet with Wernicke's original monograph, although there can be no doubt that anatomically and clinically his work contributed significantly in the slow move to 'phonology.' Paul Eling (2006) laments the fact that most of the Wernicke-like clinical aphasiological physicians in the nineteenth century neglected the work of psychologists such as Chajim Steinthal, and to this extent they have perhaps been overinterpreted as carving the way to a phonology, which would then admit of true 'phonological disorders.' Essentially, two more physicians were needed – Hughlings-Jackson (1979–80) and Freud (1891), perhaps with the addition of Hugo Liepmann (1900/1977) around the turn of the century to help keep 'apraxic' movement disorders dissociated as much as possible from language.

John Hughlings-Jackson and Sigmund Freud

One of the most significant observations in the history of aphasia was John Hughlings-Jackson's (1879–80, p. 194) claim that the fluent errors of his patients were not unlike 'the blunders' that also appear "… in persons whose speech is only very slightly defective: I mean in those who, for the most part, speak well." This passed on to Freud (1891, p. 13) who wrote that, "… the paraphasia observed in aphasic patients does not differ from the incorrect use and the distortion of words which the healthy person can observe in himself in states of fatigue or divided attention or under the influence of disturbing affects…." Thus, 'continuity' was established between persons with pathologies and those without. The 'slip-of-the-tongue' since those years has become an earmark of the description of fluent segmental and lexical 'lapsus linguae.' Accordingly, this 'continuity' between the health and the diseased has played a role in the very notion of phonological disorders, and plays a very important role in the connectionism of Dell et al. (1997a,b). We will have more to say on this later in our article. But, for now, suffice it say that the slip, too, helped pave the way for characterizations of what could be a phonological disorder. See Buckingham (1999, 2006) for extended treatments of slips-of-the-tongue and the 'continuity' thesis.

At this point, we must mention two additional players in the nineteenth-century harbingers of phonological disorders. First, all readers of Freud's monograph on aphasia (1891) will note the influence that the linguist, Berthold Delbruck, had on Freud's growing appreciation of the role of the linguistics of the neogrammarians in the study of aphasia. One piece of irony in all this is that Freud credited Delbruck for his linguistic analyses that well pertained to aphasia, while Delbruck himself admits that many of his early ideas of language production came from Jacques Lordat (Bay, 1969).

Aside from Delbruck, another important influence on Freud of the continuity between the pathological and the nonpathological came from Jean-Marie Charcot's studies of the hysterias. Freud took careful note when visiting Charcot's clinic at the Salpetriere in Paris between September 1885 and February of 1886, of Charcot's 'hysterical' patients who had *no* known nervous system damage, but whose behavior mirrored much of the hysterias of patients who had discernible brain pathologies. Charcot considered that for the 'nondiseased' subjects there was a 'functional' lesion and that as Hughlings-Jackson had noted for slips-of-the-tongue, the disruptions were psychological in nature and therefore needed a descriptive vocabulary at some remove from the physical level. Our point again is that nearing the end of the nineteenth century, a more proper understanding of the mental level of description was coming into vogue that would further delineate a phonological disturbance.

On final player in this is the neurosurgeon, W. Allen Starr (1889), who, in a long paper with many samples of fluent paraphasias, put another nail in the coffin of physical locations for fluent paraphasia. No one had then, or even now for that matter, made a localization claim for the 'functional lesion' that would give rise to slips-of-the-tongue. Starr's patients, and others from the literature he incorporated with fluent, sensory aphasia, had a panoply of posterior lesions that subtended the first and second temporal gyri, the inferior, angular, and supramarginal. He even noted some patients who had additional occipital lesions. Suffice, it says (Buckingham, 2006) that these phonological disturbances were pinned by a 'functional' lesion, and thus, for these cases strict localization was out of the question. Abstract mental levels of descriptions were becoming more fashionable for the physicians in agreement with Hughlings-Jackson and

Freud, and at the same time, the linguistics of the neogrammarians was developing along similar functionalism for historical language change, dialect differences within languages, and child language acquisition. The analyses of aphasia were consequently deepening along the lines of a mentalism, not unrelated to what Herbert Spencer had introduced decades before.

Hugo Liepmann

Ever since Hugo Liepmann (1900/1977) sketched out his initial model for three levels of acquired/skilled movements and their disorders, there has been a certain intractable overlap with language and speech. These movement disorders were characterized by lack of praxis (a+praxia). The hemisphere for these movement skills is normally the left and, as language and speech, are acquired cognitive skill sets. Moreover, there has always been a degree of anatomical propinquity between the two, and consequently both often co-occur in pathologies of the dominant hemisphere. Further, with modern models of embodiment and cognition, the two have become even more intertwined. Despite quite a bit of recent rearranging and subdividing of many apraxic syndromes (e.g., Heilman (2014, in press)), there is still some overlap with the disruptions of phonological processing in Wernicke's and conduction aphasia. These most often are the 'ideomotor' apraxias, and teasing them apart from phonetic/phonological disorders in aphasia is often tricky business. We offer this as another harbinger of phenomena that may color phonological disorders. Lesions in the left temporal lobe causing posterior fluent/sensory aphasia often cause as well interruptions of desired actions, whereby transmission of the willed actions to left premotor areas fail and thus become part of the syndrome of Wernicke's aphasia. Conduction aphasia and Broca's aphasia may also bring along an ideomotor apraxia interfering with the volitional control of limb (upper) movement on either side of the body. Although not necessarily involved in phonological disorders, we would point out the often proposed conflation of the articulatory aspects of Broca's aphasia with an apraxia of speech related most closely to an ideomotor apraxia. In fact, several researchers have likened Broca's 'aphemia' with an apraxia of speech (LaPointe, 2013), and one must admit that Liepmann considered the glosso/labio/pharyngeal muscles of speech to be limbs, although these limbs act in tandem and in 'center line' fashion as opposed to the arms.

Late-Nineteenth Century/Early Twentieth Century

The Phoneme

Although phoneticians such as Henry Sweet and scattered others hit upon the concept of the phoneme, they did not *use* the term as such. It was through the work of Baudouin de Courtenay (1885–86/1972) with his explicit differentiation between the phone (= the sound) and the 'fonema,' from the Russian (Robins, 1967). He did not conflate phonemes with graphemes, as many had done before, and more importantly used the important taxonomic prefix 'allo-' (one of a group of similar items, together which constitutes a structural unit). Therefore, what resulted was a very important three-level distinction between a phone, which, at the lowest level was understood as an element on its own – its individuality. This scatter of phones was later groped into allo-phones, which were then understood as a set of phones that structurally comprised a phoneme. As Robbins (1967, p. 204), the phoneme did not make its true impact until the work and popularity of De Saussure. Subsequently, there was some reluctant to accept this somewhat enigmatic concept – it existed and it did not. Although the early twentieth century phonetician, Daniel Jones, in 1914, made the difference between the allophone and the phoneme, his basis for distinguishing Henry Sweet's terms for 'broad' and 'narrow' transcription, there was some debate as to a kind of 'psychological' reality for the phoneme. Some phoneticians felt the phoneme to be a physiological entity. Others thought it to be a kind of "transcendental entity," while others simply felt it to be "… just a mere descriptive invention" (Robins, 1967, p. 204). Nevertheless, through the further work in the 'Prague School' tradition by the Viennese scholar, Nikolai Trubetzkoy in the years 1923–39, the phoneme because appreciated as a linguistic concept and accordingly was said to have a 'psychological' reality (Trubetzkoy, 1939). Principles of Phonology – (Trans. From the German "Grundzuge der Phonologie").

During this time, Edward Sapir (1925, 1949), as well, published his supporting views of the psychological reality of the phoneme. Without the phoneme, the nature of a phonological disruption could essentially only flourish in terms of a rather vague notion of 'the sound.' The consequences of this discovery had immediate consequences for aphasiology and the deepening of the analysis of the fluent phonological disorders in the sensory aphasias.

Roman Jakobson

Without a doubt, the transition from the Prague School to aphasiological theory in the United States came off the pen of Roman Jakobson, who, together with Gunnar Fant and Morris Halle, influenced the ongoing work at the time, which even extended into Russian, with the work of R. Luria. Early on, however, Nikolai Trubetzkoy, a fellow Russian linguistic, had paved the way for Jakobson to get into the circle in Prague, where he slowly left poetics and transitioned into structural linguistics of the day. From structuralism we see the movement into a more generative framework, where all levels of language were interwoven with a rule system, which described and extended phonology, phonetics, and acoustics into morphology and syntax. The neogrammarians of the latter part of the nineteenth century had tied together, synchronic (at one time) and diachronic (across time) studies to show interrelations between the major languages and their dialects, child language acquisition and historical change. Startling similarities in the processing of linguistic elements at all levels were immediately recognized. The linguists had also become engaged in the search for recognizable patterns in aphasia, as we have seen in the nineteenth century. This was notably extended in the aphasia investigations of Jakobson (1964).

Jakobson not only initiated early statements of syllable phonotactics, but he also utilized the new series of subphonemic features, which then provided a subdefinition of the

phoneme as being a bundle of features, a minimum of which could serve to uniquely identify each phoneme, while additional features could further refine the elements of the phoneme. The features often specified place of articulation in combination with acoustic spectra that could be correlated. So, Jakobson originally used (acute) and (grave) to distinguish the coronals from the labials and the velars. Features of voice, place, and manner were often the major features, marked as binary [+/−] to allow different arrays to minimally distinguish phonemes from one another. The feature itself became extremely useful as a measuring tool of segmental/phonological errors in phonemic paraphasia in fluent phonological disorders. As well, Jakobson borrowed heavily from the structuralism that combined Prague school phonology, the foundations of generative phonology, with notions as well handed down from centuries of Aristotelian association psychology.

In transitionalizing from poetics to linguistics, we glimpse Jakobson's contribution in light of his literary and stylistic studies of meaning to the scaffolding of the artistic scaffolding of meaning onto the study of language. He comfortably navigates tropes and turns them into linguistic dimensions. He made use of frequency of occurrence, the contiguity of elements and the similarity of units. Also, from the association psychology, Jakobson contrasted the 'syntagmatic' dimension with the 'paradigmatic' dimension, where the syntagmatic stemmed from the associative notion of linear order, serial processing, and associative chaining, and the paradigmatic dealt with similarity of form.

Jakobson transposed metaphor and metonymy into his paradigmatic (vertical) and his syntagmatic (horizontal) systems, where the paradigmatic, like metaphor, was based on meaning similarity. His metonymy brought in the most important associative process of Aristotle, which was contiguity – itself not related to meaning similarity but rather to a collocational process whereby reference was based on spatial nearness. Although most would agree that he pushed this distinction a bit too far when he tried to distinguish motor and sensory aphasia in terms of contiguity and similarity – the syntagmatic and the paradigmatic. The phonological disorders, our main theme in this article was one of substitution between features of one value difference (i.e., similar phonemes sharing all but one feature) – the phonemic paraphasias. As well, the sensory/fluent aphasias were replete with substitutions of words bearing similar lines of meaning – the semantic paraphasia.

No one familiar with phonological disruptions in aphasia can fail to note the early contributions of Jakobson as a combination of structural and early generative phonology. From his work on, the frontal lobe motor aphasias disrupted syntagmatic processing, while temporo-parietal lobe lesions gave rise to errors of either phonological similarity or semantic similarity (Buckingham, 2010).

As a modern reflex of Jakobson's model came the publication of Sheila Blumstein (1973), who benefited from his (as well as from that of Harold Goodglass) personal interest in and criticism, assistance, and advice to her while she was a doctoral student at Harvard. Measuring feature counts in the phoneme errors of Broca's, Wernicke's and conduction patients. Across the board, Blumstein found that a great majority of phoneme substitutions different minimally in only one feature. This shows that phonemes of similar bundles of features often substituted for one another, and differing only in one of those features. The feature (sonorant) soon needed to be added for further distinguishing phonemes in substitution errors. Often, an additional redundant feature (not needed in minimally distinguishing some phoneme) was the feature involved in substitution errors. Eventually, groups of features came to serve as specifying 'natural classes' of sounds, such as (+obstruent, – continuant) for the natural class of oral stops, thus separating nasal stops from the oral stops. In this way, we can clearly see that Jakobson's model began to add to what would characterize a phonemic disorder. Admittedly, Jakobson got into trouble restricting his syntagmatic disorder to the motor aphasias, since there he was interesting in serial order articulatory concatenation – not unlike Lordat and Wickelgren. In contradistinction, the phonological disruptions of the presumed fluent aphasias were replete with serial ordering derailments, but at the level of the phoneme, which we have already mentioned were signposts of phonemic paraphasia, where the errors were along both dimensions – for phonological breakdowns: substitution of phonemes and linear transpositions. Moreover, Blumstein's (1973) thesis charted large numbers of substitutions of phonemes in most aphasia syndromes.

Nevertheless, in a span of 2 years, Lecours and Caplan (1975) pointed out several problems in Blumstein's analysis that then reflected on what Jakobson had claimed. Nevertheless, the point here in our article is that Jakobson's phonology went a long way to characterizing phonological disorders – until problems with his model were discovered. As goes phonology, so go phonological disorders.

Slips-of-the-Tongue in the Twentieth Century

Essentially, except for a few nuggets in the first 60 years of the twentieth century, works on slips-of-the-tongue waned. In fact, Fromkin (1973, p. 14), in one of the most scholarly introductions to a volume of reprinted papers on lapsus linguae, writes, "There have been more papers utilizing speech error data written by linguists and psycholinguists in the last five years than in all the previous years of linguistic history." Our article, then, picks up this resurgence of the 1960s, hooking them historically back to Hughlings-Jackson, Freud and the others we mentioned above. Our point then, as is our point now, was that the study of slips not only paved the way for phonology and thus disorders of phonology, but present students have again emphasized the 'continuity thesis,' thus maintaining the connection between health and disease, and therefore in our case between the slips of the healthy and the phonemic paraphasias of the diseased. In the spirit of the present article, Fromkin (1973, p. 35) wrote that most segmental (and lexical for that matter) slips are, "…errors which appear to be solely phonological in nature, thus suggesting partial independence of phonology from other grammatical components." This 'phonological' mature is the modern day reflex of what Hughlings-Jackson and Freud were saying, except, as most know, Freud was quick to fail to notice that most often phonological errors were at the base of the generation of words and phrases that Freud tagged as driven from the troubled unconscious of his

patients – most often with sexual interpretations by him. Nevertheless, we demonstrated the fluent segmental errors of his patients with aphasia, whose 'blunders' were at a higher level of mentality and, if we take Starr's words, "resisted any clear cut location of lesions…as opposed to the motor aphasias of the day." Thus, phonemic paraphasias carried the linguistic stamp of segmental slips, and the higher cognitive levels were allowed to flourish at a mental level, thus holding to Herbert Spencer's theories of mentality and physicality.

However, the papers reprinted in Fromkin (1973) did not concentrate on aphasia, since the early papers there were more of a linguistic and/or psycholinguistic nature. Later, in Fromkin (1980), there were additional more recent studies that linked to the slip modeling of Garrett and Shattuck-Hufnagel in the 1970s and even more interesting to the connectionist models that would take hold a bit later on. We mentioned earlier that essential to all connectionist models was a *sine qua non* acceptance of the continuity theses, since those computation models had to be programmed first to simulate the normal patters, and those patterns were not culled from aphasia, but from the language of nonpathologically compromised speakers. Only then, could the IA models of Dell or the somewhat more cosmic Hopfield net architectures of the physicist Paul Smolensky's and his 'harmony machine' (see Goldsmith's brief but penetrating descriptions of Hopfield's contribution, 1990, p. 11ff). We will have a few more words on connectionist systems, mostly the IA work of Dell and his colleagues as it opens up a myriad of observations, predictions, and simulations of aphasia – mostly the fluent categories. One interesting observation from the Dell and Reich paper in Fromkin (1980) is the prodrome of Dell's connectionist work in from within the Stratificational model, constructed from the work of Sidney Lamb (1966) and explained to linguists by Lockwood (1972). If our readers want an interesting view of how Lamb's model in a way helped pave the way for Dell's later IA models. We mention this simply as another example of the continuity and change in the psycholinguistic modeling of human language and its disorders.

As we close this section, we would suggest that before reading more on spoonerisms, or exchange errors, which we will outline later with the work of Garrett (1984) and Shattuck-Hufnagel (1979, 1987), the reader should consult what we feel to be one of the first sophisticated and in-depth looks at the linguistic and computation nature of the spoonerism by MacKay (1973), reprinted in Fromkin (1973). For a full assessment of Wickelgren's (1969) paper on context-sensitive elementary motor response units and how it fails, the MacKay will make it abundantly clear that data from slips-of-the-tongue can be devastating for any type of context-sensitive, localistic, finite state automaton, even at the level of articulation.

The Serial and Hierarchical Model of Merrill Garrett and Its Sequalae

In Buckingham and Christman (2008, p. 136) in our section for further readings, we wrote of Garrett (1984) that his paper, "…represents one of Merrill Garrett's first forays into aphasiology, where he demonstrated how his serial model of sentence production could serve to characterize paraphasias and locate the principle production levels involved in their generation." There had been one paper published earlier (Garrett, 1982 in A. Ellis (Ed.)), where Garrett wrote on errors of speech, but where he again began to look at speech production data from "normal and pathological language." Our present article has maintained that models based solely on the slips-of-the-tongue in typical speaker–hearers of a language who have sustained no pathological insult are cast at the phonological levels. The continuity thesis assures the reader that models of this sort are cast largely at the level of human language phonology (both the formal and the segmental sublevels) and that they may be incorporated to describe and explain the paraphasias (both lexical and segmental) of the fluent/sensory aphasias. Based as they were originally upon slip data, models such as Garrett's made no commitment as to anatomy at first, and only later when they began to make correlations of the distinct symptomatology for the lesion locations from the clinics of these adults with aphasia. In fact, Garrett's model remained essentially a serial functional one, where lesion location was of secondary concern.

This goes for connectionist models as well; they are functional in nature although many PDF connectionists are mistaken when they claim that they are simply replacing a computer metaphor *for the mind* with a computer metaphor *for the brain* (Fodor and Pylyshyn, 1988, p. 62, ftn 35). Fodor and Pylyshyn write (1988, p.62, ftn 35) that, "… the issue is not at all which metaphor we should adopt; metaphors (whether 'computer' or 'brain) tend to be a license to take one's claim as something less than serious hypotheses …. The claim that the mind has the architecture of a Classical computer is not a metaphor, but a literal empirical hypothesis." We also should bear in mind Pylyshyn's (1980) distinction of the computer models programmed by computer scientists and the computer models programmed by psychologists. The computer scientist's program for playing chess, for example, is successful if the computer can beat a professional human chess player, without worrying whether it does so 'like' the human. The psychologist, on the other hand must go a step further and claim that the computer should behave like the human it simulates. Garrett had none of these commitments, since his model did not even hint at 'Hebbian Learning,' whereby Hebb wrote, "When an axon of Cell A is near enough to excite a Cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased" (cited in Buckingham, 2002, p. 287, see further references there). Garrett's model was a classical psycholinguistic construct for sentence processing, but existing as it did to imply performance and not competence; it had no commitment to computers or the brain. It nevertheless finally allowed linguistic aphasiologists the more closely characterized phonological disorders, where we should include the conceptual level as well as the phonemic form level. Lexical substitutions, accordingly, can be constrained from above by showing semantic similarity and can be constrained from below by showing phonological similarity. Our article, however, is focusing on the segmental rather than the lexical error, but this distinction is often blurred.

Figure 2 shows the overall levels and note the rough agreement with the architecture of J. Lordat's model discussed earlier. His model and its features represent real-language processing examples culled from his and others collected slips-of-the-tongue, produced online by speakers. He also holds to no a priori assumptions on the relations between formal grammar (see Levelt, 2008 and processing structure).

Figure 2 shows the overall set of levels in Garrett's (G) model. We are focusing on the development of modeling that provides functional commitments to phonology and therefore can locate the lexical and phonological processes and disorders in the model nevertheless build upon slips-of-the-tongue on the assumptions of the continuity theses. Note that both the serial models and the connectionist models we will discuss shortly accord with the now established continuum from health to disease, or put another way, from normalcy to pathologically compromised. Again, Buckingham (1999, 2002, 2006) provides more historical evidence for this thesis. A more detailed and succinct summary and comparison over some 20 years of work with serial and connectionist of Garrett, Dell and Levelt, and others is presented in Nickels and Howard (2000).

The top and bottom levels in Figure 2 of Garrett extend his model from the conceptual to the motor control processes. The conceptual and message levels are more pragmatic in nature; less built on slips per se, and, anatomically, would have to cross over to the right hemisphere, where discourse structures are determined by the inferential processes. These high-level processes determine as well as speaker's current perceptual and affective states as well as the ability to access schematic memory for information such as world knowledge. These levels map to the set of logical and syntactic processes. The derailments at these points of pragmatically for discourse, speech acts, implicature, structures more often misaligned in the dementias or in right hemisphere aphasia and thus do not directly affect the phonological disruptions treated in this article.

Figure 2 The overall hierarchical scheme of Garrett's model.

At the bottom, Garrett places the motor-coding processes that produce articulatory representations, which subsequently map to subcortical and cranial nerve systems. Slips here do not play into the structures so crafted, which as we claimed is the same case at the very high levels. The processes and levels between these are what we are focusing on for phonological disturbances. Garrett claims that these middle processes and the representations they give rise to are his 'sentence processes,' which in fact are his main focuses. His logical and syntactic processes build the initial linguistic structure. It is prearticulatory argument structure is at issue here. The calculus of $f(x)$ is built of atomic predicates, with a minimum of one predicate and one argument. Much has been written about argument structure at his level, where the argument or arguments are set in their functional/role vis-a-vis the predicate. Some say, as originated by Charles Fillmore (19 68) that some sort of 'subjectivalization' occurs, whereby one of the arguments will transpose around the predicate to become 'the subject' of the sentence, in an SVO language, which is the way English works. Of late, Chomsky has conflated these kinds of 'movements' with others a bit more typical of his earlier work. From Fillmore's case model, we can glimpse the prodromes whereby verb and noun selection must ultimately provide an utterance order where comprehension will involve linking the arguments to their semantic roles (agent, object, source, goal, experiencer, theme, location, dative) depending upon who is constructing the model and upon issues of whether agents overlap with being sources and goals being objects or datives. Often comprehension disabilities of Wernicke's aphasics involve the acquired associations between the predicates, the arguments, and the surface positioning of those arguments. What we have here in Garett's terminology is the functional level representation; it is still preutterance. The syntactic and phonological processes map from the functional- to the positional-level representations, where utterance word order is now in place. The positional level representation contains ordered and labeled frames for the content word lexical items, the frames coming with the fully specified grammatical morphemes – the way most believe. Garett points out that segmental slips-of-the-tongue and segmental phonemic paraphasias in the fluent and sensory aphasias are the derailments of the phonological (not phonetic yet) segmental ordering processes. The positional level in this model still only incorporates abstract forms, words, phonemes, and morphophonemes. Common slips-of-the-tongue here of words in sentences such as "He put the stove on the pot." The common phonological slips and paraphasias most often involve derailments of the phonological processes of segmental ordering, deletion, addition, or substitution. Phoneme ordering errors may be anticipatory, where a preprogrammed phoneme is anticipated

and makes a prior entry into the produced string. Sometimes the moved segment will simply be added to a word, deleted from it, or produced once again – a perseverative error. Note that these added segments come from somewhere in the target word itself, and again come from the nearby context. In slips-of-the-tongue, many exchanges often referred to as the 'spoonerism.' Exchanges, it turns out are rare in phonemic paraphasia, but not in the normal slip. MacKay (1973, p. 186) provides an explanation for why the adult with phonological paraphasia may produce only a few exchange-type errors. There he posits that a fusion of the two phonemes never occurs, which might be expected for a phoneme exchange, but he has suggested an ordering mechanism that metaphorically 'scans' (a mechanism borrowed from visual cognitive systems by MacKay, (p. 183)). In his seminar paper, MacKay writes, "The form of the scanning mechanism was arbitrarily chosen, pending further research." We mention the scanner metaphor at this point in our article because the further research apparently continued to justify the use of this cognitive visual metaphor (see Buckingham, 1986, 1995); it worked well until the connectionists appeared on the scene. It soon became clear that the scanner not only scanned the segmental units in its range (or as MacKay writes (p. 183, it 'sweeps' over the range) of motor engrams in a one-direction anticipatory (it looks 'to the future' in recent terminology), bringing them to threshold. Here, both Garett and MacKay would posit that there must be a kind of 'copy' of the segment. When speakers are not subject to brain damage many forces come to play in the spoonerism. In the uncompromised speakers, the segments scanned are already in a proper serial order. This so-called "first" ordering comes ready-made and ordered with the original selection of the "word" in its prearticulatory form. Subsequently, the phonemes will be scanned and copied during a second serial ordering, unavoidable in these psycholinguistic serial models. The second concatenation will be correct as long as long as the scanner operates in a sufficently slow manner, as MacKay (1973) makes clear. Processed without overarching speech, the normal speaker will produce no phoneme exchanges, i.e. spoonerisms. The slip-of-the-tongue occurs because if there is a relatively close range between the exchanged segments, where the one in 'the future' has tonic accent may cause it to reach threshold sooner than the phoneme preceding it, which is most often at least not the tonic accent – even though it may be stressed. This stress-dependent transpositioning over a relatively short range of items between the exchanged items is quite normal in the slips of nonaphasics. The reason for this is that the spoonerism must depend upon normal. MacKay builds into the scan-copying mechanism a normal reciprocal inhibiting capacity so that the exchange to play out. When this mechanism is not derailed, for example, in a non exchange for a slip, but where the second element is inhibited from moving out front and in this case it simply remains in its position, causing only the anticipatory slip. This then would not be an exchange but rather what some have called a 'doublet' creation (see Buckingham, 1989 in Nespoulous et al. (Eds.)). The point to make here for the purposes of our article is that the spoonerism that is produced must count on the working of this reciprocal inhibitory mechanism. Adults with phonemic paraphasia do not produce nearly as many spoonerisms as do adults without aphasia. The theory is that the aphasic derailments destroy this special normal process and therefore instead of the exchange, we more often see the first movement (the anticipation) but that initial phoneme that was bumped out of its initial slot cannot be held on to long enough for its 'post entry.' This is the crucial process. When the element that is anticipated is activated earlier, the original initial phoneme becomes 'hyper excited' and the expected rebound of excitation is sometimes sufficient to then allow the original displaced segment to then be copied into the vacated slot, thus the exchange occurs. According to Mackay's scheme, the rebound postexcitation discharge, which often occurs during the interaction of similar phonemes, can allow the placement of the earlier phoneme a kind as a 'post entry,' copying it now into the vacated slot of the anticipated segment. Again, the point here is that the phonological aphasic derailment will prevent this normal type of error, and therefore we see only a very few true exchanges of phonemes in paraphasia misordering errors. By the same token, one actually observes many more spoonerisms than 'doublet' creations in adults without aphasia. The Mackay (1973) is a must read for a proper understanding of what would be a more likely slip-of-the-tongue and what would be likely in a paraphasic phonemic serial ordering error. At the risk of being 'parochial' (or 'trite'), we would claim that all the disordered phonemic transposition in adults with phonological paraphasia do, indeed, 'look normal' in terms of their obedience to the 'phonotactic' patterns of the native languages of those adults. Although we will only briefly touch upon the competence model of phonology referred to as 'optimality theory (OT),' and its mappability onto the harmonic Hopfield Nets connectionist architecture of Smolensky, we will touch upon a presumably more profound deepening of just what phonotactic constraints may entail, and they appear to entail it for both optimality competence theories as they might square with the distributive and nonsymbolic connectionist models of psychologists qua physicists, such as Smolensky (1988). These are qualitatively quite distinct from the non-Hebbian, IA architectures of Gary Dell and his colleagues. We will also briefly discuss the latter models, which have had great success in describing and explaining a wide swath of phonological paraphasic errors – many of which deal with segmental ordering, both anticipatory and 'carry over' or 'perseverative.'

Figure 3 in the Garrett model shows the internal structure of mapping from the 'message level' of representation to the 'functional level' of representation.

Here, two processes unfold, much of it in parallel, which is a thorn in a serial model. Nevertheless, at this level, words (the content) are selected on the basis of their amorphous meaning along with the determination of linear slots (frames). The frame and its contents here are abstract and show the logical relations of words in their functional order – which is not truly and order. Here, the amorphic words are 'assigned' to a deeper logical and relational order. Based as these levels are on slips-of-the-tongue, at this level we have either a phrase length frame or a small clause, which may indeed have two deep sentences. At this level, slips look simply like meaning-based lexical substitutions within one slot. The slips here, of course, have no phonological similarity, since we are at

Figure 3 Sketched here are mappings from the inferential processes through the message representation through amorphic semantic lexical selection and the determination of functional frams. a pre-prearticulatory level. There can also be word-exchange slips, which cross over sentence boundaries, often simply infinitivals such as "[Cat, it's too hungry [for you to be early]], where there is an S(entence) boundary between 'hungry' and 'for.'" These kinds of slips can cross prepositional phrase boundaries as well as a conjunction S boundary. Although we see many semantic substitutions in fluent sensory aphasias, we see fewer word-exchange errors in aphasia, and we would claim that the exchanges of words likely have to have sufficient normal processing to occur as we saw with the spoonerisms of MacKay. Again, all this processing is quite removed from the utterance. It does provide us within Garrett's model of a 'functional level,' which is roughly of the form of deep case or argument structure, where all is relational with no linear order. Needless to say, there is a plethora now in the syntax and semantics of case grammar, thematic roles and the 'syntacticon' of predicate/argument structures and co-occurrences. Here, the 'syntax' is the frame order (non-utterance) and the 'ticon' is the lexicon aspect of it all. For, example, verbs are often said to be stored in the lexicon in terms of the typical arguments they code with. And, of course, in a model like this we would have to have some kind of statement as to which argument would show up in the position of the subject, etc. That is more in line with the pragmatic needs of the sentence producer. But that is quite another story for the purposes of our article.

In Figure 4, we approach the next levels of representation, where now the functional level maps to the positional level. Although we have both words and frames in this mapping as well as above, we are now working into an utterance order – albeit still prearticulatory. This is an extremely important point because the model is readying the words based on their phonological properties and those words are considered to contain their phoneme and morpheme building blocks. Since phonemes are not sounds but abstract sets of sounds, and consequently, we should not blithely conflate the phonemics with the phonetics – although we are entering into somewhat murky waters, since some believe you cannot tease the two completely apart, and some, such as Ohala (1990), deny that there is any 'interface' whatsoever between the two; they are hopelessly intercalated.

The lapsus linguae from which Garrett's original architecture was proposed and the continuity thesis extend once again into the symptom-complexes of phonological disorders, which mirror the processes that map the Functional Level Representation onto the Position Level Representations in his serial model. In the Garrett model, this is the crucial nexus for phonemic paraphasias. We imagine what is going on with the following serial jargon of the model, with an eye toward later considering its worth when confronted with its replacement by connectionist simulation in our historical approach to phonological disorders within neurolinguistic cognitive science, which we would claim is a telescopage of Caplan's (1987) neurolinguistics and linguistic aphasiology.

First notice that there is a retrieval of word forms, which is the second lexical lookup, but this time it is the phonological structure of the word. We do not say that this is after the meaning based word is selected, since the point will be that this are dissociated from one another. They are dissociated when speakers 'know what they want to say' or 'know what the word is,' but cannot retrieve the form despite this. Nonbrain damaged adults do it, adults with aphasia do it, and Alzheimer's patients do it. There is nothing new to this, since the

descriptions of the state of mind of speakers in this disconnected puzzle are legion and go back centuries (Benton, 2000, Chapter 7).

Positional-level planning frames are also encoded. These come with their Fo contours, where the tonic accent has been established at the message level, since, for example, if there has been stress movement, contrastive stress, or where the major pitch change (at least for English) has been relocated for pragmatic purposes. Here it simply comes coded as the sentence is being readied for a closer approximation to utterance order. The frames are coded with grammatical category marks, and affixal morphology, which is nevertheless, in a preaccommodation morphophonemics of sort. This is not only because eventually Garrett want to handle agrammatism as best he can, but also because the morpheme slip-of-the-tongue phenomena show that morphemes can move or be deleted, and the root forms to which they are underlyingly attached accommodate to the morphological alterations. The range of these frames are small clauses, not unlike the message-level logical frames – except that the material here is abstract-form based, since we are at the second lexical lookup for 'words' at this level. An 'abstract' form base should not be a contradiction, because the forms here are phonemic or morphophonemic. At this point, we consider how the model gets the words into the frame slots.

Here, we see a slotting of words: includes situating the segmental units in their normal serial order. This is to say, major processes of serial ordering for utterance order take place here, and as the reader can tell from examining **Figure 4**, there do not seem to be any ways to do this. Naturally, and with the contribution of Shattuck-Hufnagel (1979) and others, three mechanisms were conceived to operate here. In fact, these mechanisms were necessary for the models to describe the actually serial ordering. We have discussed anticipatory slips in spoonerism, with the additional complex intactness of super activation and quick erasure to get exchanges over short ranges through. Recall that the exchanges are most always over short ranges of words. It was in the Mackay paper that we introduced the notion of a 'scanner,' which could look over the range of material to locate the material to be situated into the frames. In its normal function, it looks 'ahead' most often and when it goes awry, the error transposition is one that 'moves from right to left,' which means it gets situated earlier than usual; it comes from the 'future,' and enters the 'present' in new terminology from Dell's work, although we will see shortly that IA is philosophically, computationally, and functionally opposed to serial models. Nevertheless, Lashley (1951), saw the need for anticipatory error in normal slips-of-the-tongue. They are seen in aphasia as well, with one very importation that has come to light from deeper looks at slips. We will discuss this

later in the article when evaluating Dell and Martin's contributions.

Again, for our purposes in this article, phonological disorders are captured by the 'scan' mechanism. However, to finish off the delivery processes into the frames, we must add the obvious fact that the items are 'situated' in these frames, and most feel that this should be part of the scanners operation. Accordingly, the mechanism came to be called 'the scan copier'; it scanned and copied 'the seen' items into their frames. MacNeilage (e.g., 1998) has written at length on slot/frame and their contents in speech production as well in the evolution of human speech. Syllable constituency, too, must be nestled at this junction, since slips-of-the-tongue as well as phonemic paraphasias are sensitive to the constituency. However, it goes without saying that how different models handle syllables may be quite varied, and those models will color how one explains and describes the 'housing unit,' which is the syllable (Meyer, 1990, 1991, 2000; see other contributions in Weldon (Ed.), 2000). Some investigators focus on an absolute necessity of the vowel portion (the NUC of Prince and Smolensky (2004, p. 33), with the universal CV where although not necessary for all languages (thus not absolute) and a CVC with a final coda consonant; these constituencies are much rarer. This view of the syllable stems from 'OT' (McCarthy (Ed.) 2004), which we will briefly mention later. Still others opt for a binary constituency of onset + rime, where the rime consists of the vowel ('nucleus') + coda (Buckingham, 1986). A strict adhesion to one and only one theory of syllable constituency is unwise at this point in our knowledge of speech production. In short, the scan copier must be sensitive to syllabic slots within the utterance, the boundaries between the syllables and the metrics, which would adhere to the overall prosodic structure of the resulting positional level representation.

Admittedly, the scan copier as originally characterized did not have the capacity to appreciate phoneme similarity, since that would have involved subphonetic manipulation and the ability to keep in mind feature sharing counts. The scan copier worked essentially on the segmental level and not on the feature level. Substitutions in adults with aphasia seemed to favor interactions between phonemes differing minimally, more often differing by only one feature. Blumstein (1973) as we claimed earlier found more substitutions with fluent aphasias, but of those that were made by Broca's, Conduction and Wernicke's had similar statistics, favoring the one feature differences. Similarity will turn out to be more easily captured with the continuous numerical values referred to as 'weights,' whereby the weights of /b/ and /p/ would be closer in value that the weights of /b/ and /k/, given that the frequency of occurrence of these phonemes were the same.

Now, the question comes as to how to get rid of the phoneme once situated (copied) in its slot. Thus, a 'checkoff' monitor was conceived to make sure that once a segment was slotted – correctly or incorrectly – this monitor would eliminate that segment (Buckingham, 1986). This, too, would become more easily handled by a manipulable 'decay rate' in connectionism, whereby the segment could be checked off at a rate, which in turn could be fixed to work overly fast, overly slow, or in a normal rate that could be determined by simulating either that would maximally work with upcoming slotting, but could then be fixed to simulate a breakdown whereby the segmental was checked off overly fast or whether it would be checked off overly slowly, which may begin to compete with new stimuli or otherwise be activated a second time. Decay rates as continuous connectionist checking off would become an important addition to connectionist systems.

The phonological disturbances were not at least describable in terms of breakdowns in the mapping computations that structured the positional-level representation from the functional level of representation. Phonological paraphasias could be substitutions, linear ordering errors, both anticipatory and perseverative – looking ahead to the future and bringing an element to the present or holding on to some element in the (nearby) past and copying it again in the present if not checked off by the monitor. Most often, an item will be anticipated but the monitor will fail to check it off, thereby creating a 'doublet' of the segment or segments (Buckingham, 1989). Often the derailments are severe enough to prevent recognition of the target. That is, the error cannot be related to a target, otherwise with less-severe errors, the target can nevertheless be gleaned. The accounts of so-called 'target-related' errors are rather straightforward. On the other hand, nontarget-related errors present a greater challenge to analysis. Often, these nonrelatable errors are categorized as 'neologisms.' Although a strict dictionary definition of a 'newly created form' is a 'neologism,' target-related errors are unfortunately logged as neologisms as well. We refrain from this confusion, and would claim that the less severe error where the target is recognized is not technically in the general aphasiological usage referred to as a 'neologism.' For example, 'neologistic jargon' is not restricted to target-related errors. The neologism has been enigmatic and has always required a good deal of caution in its analysis. Early Boston Diagnostic Aphasia Exams simply considered the neologism to be operationally defined as a form whose phonemic makeup was over 50% off from the target. But, note here there was great difficulty, because the target would have nevertheless had to be recognized in any event. That type of account nevertheless claimed that the neologism was produced all and only by phonemic distortion of a word. Buckingham (1977) questioned the exclusive recourse to phonemic errors, which had come from the work in Kertesz and Benson (1970) and came to be known as 'the conduction theory' of the neologism. An additional proposal then followed such that a neologism may have arisen through a more complex breakdown that included the possibility that there was a first lexical lookup, but that second lexical lookup was either not retrieved or only partially retrieved, whereby other segments would have to be produced in many cases. As per Green (1969), much alliteration and assonance would color severe neology as a result of anticipatory or carryover doublet creation – imparting a 'poetic' hue to the output. Neologistic jargon in the fluent/sensory aphasias took on a life of its own shortly thereafter and different accounts arose.

Finally, with the serial models, there seemed to be no inherent reason why there would be different numbers of anticipations or carryover. Further, and very importantly, rarely if ever do the paraphasic errors result in nonpronounceable words in phonological disorders by disobeying phonotactic constraints.

As we omitted the higher pragmatic message-level processes, we will only note that the 'regular' phonological processes that feed into the phonetic representations in **Figure 2** are largely coarticulatory and general allophonic processes that take us beyond the focus of this article. Garrett was obliged to finish out these lower-level processes, since these final readying phonetic computations ultimately mapped to the actual gestural/articulatory through motor control to the needed sets of cranial nerve innervations. These levels were post slips-of-the-tongue as well as postphonemic paraphasic errors and, in fact, postspeech apraxic gestures. The kinds of breakdowns with 'motor coding processes' were the various dysarthrias described in works such as Duffy (2013).

Neologisms and Neologistic Jargonaphasia

Much has been garnered in the description and analysis of the neologisms in jargon aphasia. First off, we distinguish between 'phonemic' jargon as well as 'semantic' jargon, although both these forms are typical of fluent aphasia. The semantic jargon, where the paraphasias rest largely at the level of *word* selection, has been recently linked to segmental selection processes in that the perseveration involved with derailed phoneme and word selection stems from a common input computational breakdown of weakened activation of the words or the sounds (the phonemes, to be sure) searched for (Martin and Dell, 2007). This then scrambles the postactivation environment with 'unwanted' forms, which then 'compete' with the target on some similarity association and thus have an almost equal footing in their ability to be retrieved in place of the target. So, together with overall weakening ('deafferentation' is used by some) of target words or phonemes, there is a computational/selection misfiring, placing some recently produced error in the 'pre-checkoff' time period (early decay time range) such that it is often perseverated. Moreover, when these error forms are in the recent, postactivated, surround and if they happen to be associated with the sought after target on either a phonological or a semantic basis, the likelihood of being perseverated is enhanced – purely associationistically. Aristotle quite often rears his ancient theories in structuralist aphasia models. It is also not unusual for lexical selection errors to be associatively related to phonologically similar and semantically similar words. Even more important is that the lexical paraphasias often share even stronger associative links, since many errors (often noted in slips-of-the-tongue) link to the target along both phonological and semantic similarity. Aristotle would be quite pleased and vindicated in all this, since so much of computational strength and weakness is due to associative factors, which were discovered centuries ago (Buckingham, 2002). The interactive activational connectivity among the two lexical look ups in the Garrett serial model and in the Dell and Martin IA (symbolic) model in the connectionist paradigm is thus supported even further. The 'repeated phoneme' effect we discussed earlier, the 'lexical effect' observed in phonemic paraphasias where the errors are more likely to be produced if the error turns out to be a word. Connection weight may account for this as well as a late output monitor whose job is to check if the output is a word in the dictionary; that is all. The 'gendarme' metaphor would not go far enough if to the lexical effect constraint, we add semantic and/or phonological feature sharing as well. Weight differences would be explanatory here, since they follow the dictates of Aristotle. The Garrett model does not. This, of course, relates to the deep connections of Donald Hebb and others before him who dared to think about running associationist mathematics and statistics over computers, which could then, with programming finesse, simulate normalcy and abnormalcy in language and speech. Suffice it to say that it is extremely likely that the productions of neologisms may involve similarly tightly yoked connections between Lexical lookups #1 and #2. Since Buckingham (1977) and before, with Luria (1970, p. 296) and Pick's (1931/1973, pp. 56–57) notions of a 'two-stage error' (Buckingham, 1981, p. 48) where some coalescence within a word where the semantic is blended with the phonological, with say, some additional phonemic paraphasia, a nonrecognizable word may appear. The 'two-stage' account obviously stemmed from serial thinking early on, and therefore worded the processing in temporal terms – first a semantic selection error at the functional level and phonological errors applied to at the positional level, thereby rendering the production unrecognizable Lecours and Lhermitte (1972, pp. 304–305).

One could suggest that these neologisms stem from monemic (semantic – HB/SB) paraphasias where the lexical material is subsequently the location of a phonemic transformation.

This scenario has in one form or another come to be known as 'the anomia' account of neology. But, this explanation has more recently run into how we interpret the hesitation and halting behavior of a patient searching the lexicon. This brings us to a recent study of recovery from jargon aphasia to 'anomia.' Note first off, that the anomia end stage was first considered in depth in Kertesz and Benson (1970) for neologistic jargon aphasia evolution/recovery (Buckingham, 1977).

Recovery

Eaton et al. (2011) have recently published an in-depth study of the recovery on a patient who initially had jargon aphasia. To date, this study represents one of the most complete pictures of recovery of a single case of jargon aphasia. The subject was a 67-year-old male, who had sustained three strokes, the most severe being the third in June 2002. CT scanning revealed a large lesion in the left MCA region. The patient had a fluent aphasia with nonwords (phonemic paraphasia) and inappropriate words (often without semantic relations with a target) in paragrammatic, "… sentence-like structures" (p. 1547).

Over a period of 21 months, the patient was tested periodically on single word naming, reading and repetition eight times during this time period. Both correct responses and error responses were noted at testing and later analyzed structurally in terms of whether the words were actual words in an English language dictionary (the Collins Concise Dictionary, 2001, edition) or whether they were nonwords. The first four confrontational tests were in August and September of 2002, 2–3

months post onset. His most severe stroke in June of that year had precipitated the first aphasic disruption. At 7 months post onset, in January 2003, the final three tests were administered.

Monitoring versus Anomia

Very importantly, Eaton and her colleagues went a step further to add to their single word corpus by including three samples of connected and elicited spontaneous speech by providing the subject with pictures, which he was asked to describe – not just name. The first sample was collected within the first 7-month period – actually at 1 month post onset … July 2002. After the single word testing period, two more samples of 'connected speech' were taken at 18 and 30 months post ictus. That brings the range of recovery time closer to their 21-month period. In the conclusions to the study, the single word testing as well as the 'connected' speech samples were coalesced. One important finding was that there was indeed change over time and the authors want to suggest that there is now an ambiguity in the interpretation of the end stage hesitations, struggles, and other 'trouble-indicating behaviors' that seem to the authors to *not* indicate lingering anomia, as claimed by Buckingham (1977), Kertesz and Benson (1970), and Butterworth (1979). This 'strategic adaptation' also seemed to be observed in Kohn and Smith (1994), while two further subjects out of four in Kohn et al. (1996), "… showed no change over time." More studies are needed at the end stages of jargon aphasia to continue closely monitoring the subjects' monitoring abilities to be sure that their stalled behaviors on naming indicate blocked access to the word with egregious error productions during the block, or some periods of no-response, or some internal blockage of felt incipient errors, which are then themselves blocked so as to not produce errors. This is quite another cognitive set of affairs from a 'pure anomia,' and is clearly important in the charting of end-stage recovery abilities. We did not see end-stage testing of comprehension in the Eaton et al. study, while we note a speculation of Nichols and Howard (2000, p. 126) when they were considering the clearing of phonemic paraphasias in a case study being described – but where the patient still produced omissions semantic substitutions. They considered a possible lingering anomia, but reflected that perhaps the patient was, "… using his good comprehension abilities to monitor and edit out, formal paraphasias before they were articulated, but there is no positive evidence in favor of this."

Most of the Eaton et al. study supported other recovery findings, such as (1) more correct responses over time, (2) fewer nonwords; (3) trends where errors slowly proceed from 'nontarget related' to 'target related.' Some use the dictionary definition of 'neologism' and claim that both sets are 'neologisms,' some relatable to a target, others not so. We do not think that this usage of the dictionary definition is felicitous in aphasiology, since 'neologism' has risen to a more technical usage in our field. On the dictionary meaning of neologism, we have *any* new coinage, presumably any slip-of-the-tongue that happens to be a nonword or any phonemic paraphasia, whereby a nonword is produced by one simply change, the so-called 'target-related neologism,' (4) a suggestion that since repetition and reading are computationally easier than naming, those tasks recover better and throughout recovery are generally performed better by the subject. They take Dell et al.'s (1997b) 'global' approach to noise in the system or lack thereof for naming, repetition, and reading, with the last two dissociated from the total recall task of naming. At least both reading aloud and repeating include supplying the subject with elements of the needed response. Naming is total recall – no hints added. We would note that Dell's more recent work with deafferentation and decay rates are much less global in nature, where noise to the system is much more restricted in cognitive processing and local 'lesioning.' And, finally (5) although perseveration featured strongly in this subject's jargonaphasia, they found no *significant* decrease in perseverations over time. They recorded total word perseveration and segmental perseverations that blended with other words, nonwords or previously perseverated words in close range. Buckingham and Christman (2004) described the syllabic constraints obeyed at the splice junctures, where the perseverated material blended with another form. We are not aware of any 'prediction' of a *significant* decrease in perseveration at late states of recovery. Nevertheless, we do agree with Martin and Dell (2004) that a trend in this way is almost always seen, and therefore their 'anticipation ratio' is always higher as the patient recovers (caveat, Eaton, et al., 2011). This is an extremely important metric of recovery to normalcy in an adult with aphasia, since it has been well established that slips-of-the-tongue in nonaphasic speakers favor anticipatory errors, with much fewer carryover errors. This is empirical evidence that recovery in aphasia approaches normalcy and the 'ratio' can serve as a metric of recovery through the evolution of the syndrome. The authors do note, however, that full word perseverations did not even, "… move in the predicted direction" (p. 1554). We do not know what the anticipatory ratio was; perhaps was lower. Their blended perseverations in all tasks, "… showed some reduction" (p. 1554). Perhaps what all this means is that in fact the patients had not truly recovered as well as the authors feel, and that perhaps their 'troubled naming' was still indicative of an anomia and not so much improved monitoring and inhibiting incipient, prearticulatory paraphasias. This presumed ability needs much more investigation as to whether all monitoring behaviors were preutterance and not immediately post utterance. From the study, it would appear that the error monitor was a prearticulatory ability, which on the face of it is of tremendous cognitive significance.

It goes without saying that recovery studies such as Eaton et al. (2011) are the *sine qua non* of an improved understanding not only end stages, but also of a better understanding of the acute stage behaviors. Here, we would point out as well that Jane Marshall, second author of the present study, has contributed much of late to the overall study of jargon aphasia and its neology (cf Marshall, 2006). The reader would do well to consult that work and follow up with the reference to much prior work.

From Serialism to Connectionism

The Lull before the Storm

Before we bring in connectionism, we should mention that up until its dawn, there had been a host of modern technical

neurolinguistic studies of phonology and the brain, which did not ruminate on how the disorders could possibly be simulated on a computer. It would be useful for the reader to consult Whitaker (Ed.) (1988) for investigations on (1) how the nervous might acquire phonology; (2) how phonology may involve not only the cortex, but the subcortex as well; (3) how Alexander Luria's 'afferent motor aphasia' and conduction aphasia overlap to a reasonable degree and how they confront the interleafing of phonology and phonetics; (4) to what degree can phonetics and phonology be separated from motor planning and execution; and (5) clinical/neuropsychological studies of the specific disruptions of oral reading in deep dyslexia.

Wither Simulation

Since connectionist models have had great success at simulating aphasic behaviors that were heretofore accounted for, described, and explained with serials models, such as Garrett's. While we have previously published analyses of phonological disorders in terms of scanners, copiers, erasures of produced elements by a check-off monitor, random generators (Butterworth, 1979; Buckingham, 1981), and final output stage palace guards checking to assure that the output has only words in it. As noted earlier, Buckingham's (1986, 1989) studies of phonemic paraphasia made recourse to all these mechanisms proposed to operate among the processes that mediate the functional representations and the positional representation in serial models such as Garrett's. Connectionist programs properly structured in terms of connectivity strength (mathematical 'weights') between elements on counts of their frequencies of IA, will, with little difficulty when run thousands of times with input 'jolts' to prime the action produce with a good degree of 'faith' the response output. Guided by the continuity thesis, once fairly normal responses can be produced, the associative values of connections and their localization in the system can be manipulated in a vast number of ways to evoke distinct kinds of error patterns. Wheeler and Touretzky (1997) showed this forcefully comparing their simulations to what Buckingham (1986, 1989) described. What Buckingham had detailed using serial mechanism was computationally simulated in a much less cluttered and complicated fashion, suggesting that the serial mechanisms might just as well be eliminated as unnecessary. Further, the mathematical 'lesioning' could be done either locally or globally, with different kinds of error patterns. Altering weights at different points of the system resulted in errors that appeared to be global in nature. Altering them differently would produce 'even' more haphazard 'noise,' again producing errors of a more global nature. The system could be altered to check predictions in many ways. Weight changes with individual classes of phonemes at lexical lookup #2 could produce substitution errors, while slowing down or speeding up of decay rates could simulate perseverations of phonological segments recently activated. Speeded look ahead processing would simulate anticipatory derailments in linear order. If programmed correctly for normalcy, the outputs would often produce spoonerisms, for example, as long as the activation/inhibition parameter switch mechanisms were set according to Mackay's theories of how exchanged items interact to work correctly. Alter these systems with weight change 'lesions' and the runs will not likely produce spoonerism and will produce more simple carryover or anticipatory errors. As far as we can tell, there have not been many studies to date comparing the spoonerism with the many single segmental misorderings, where the anticipated segment remains in its original slot, thus creating the 'doublet'; out of one segment you wind up with two of a kind. Both Wheeler and Touretzky (1997) and Hillis et al. (1999) simulated the production of neologisms, but only used one location of weight lowering (weakening), which was locally manipulated from within the processes mapping words onto their phonological makeup. Small weakening only simulated simpler phonemic paraphasias, but more severe weight weakening produced more severe paraphasias, many of which reduced the input word's recognizability. Some add the modifier 'abstruse' to the frank neologism, but we note that these neologisms arose from only weakening word to phoneme links, and so did not account for a possible anomia underlying the neology, since inputs to the phonemic level in LL 2 had to be properly retrieved words at LL1.

Simulating Pavlov

In Buckingham and Christman (2007) we noted a very interesting finding by Harley and MacAndrew (1992), which seemed to have actually simulated Ivan Pavlov's 'paradoxical state,' later borrowed by Alexander Luria for word retrieval phenomena (1973), where activation dynamics triggered a reversal in stimulus/response such that seeking target behaviors would actually retrieve much weaker or peripherally related items rather than the more frequently and heavily weighted target items. These Pavlovian rules of force were three and are as follows: (1) normal rules, where proper behaviors were elicited at stimulus/response settings, (2) a phase of 'equalization' where because many response types are activated simultaneously, there was no response at all, and (3) the 'paradoxical' phase, were normal rules of force were actually reversed.

Harley and MacAndrew simulated this paradoxical state (see **Figure 5**) in cortical neurodynamics whereby random 'lesioning' with 'noise' superimposed upon a system with an already weakened weight value of the connection strengths within the semantic (conceptual) level to the lexical level in their schema (not unlike the Dell model (1997). The reader of this article will have to consult Buckingham and Christman (2007) for the details of how Pavlov altered the many processes in his 'conditioned' response learning experiments with its 'laws of strength/rules of force.' Unwittingly paraphrasing David Hartley (1746, 1749) (Pavlov (1962, p. 88) in a lecture at the Sorbonnne in 1925 wrote that, "At the present time we have facts which warrant the assumption that the idea of coupling (associating by conditioning – HB/SC) is even an elementary physiological process." This sort of modern day technological simulation of Pavlov's findings attests to the importance of connectionist work. It bears saying in closing that the paradoxical state may indeed be involved at the very least in what was causing 'ottoman' to be easier than 'chair' in the work of Marshall et al. (2001) where they found … an inverse frequency effect in jargon aphasia and hypothesized that our reversal of the rules of force (Pavlov's term) was at least somehow partially caused by the semantic nature

Figure 5 Graph is the result of a combination of connectionist lesioning by "random noise" added to already weakened connectivity of lexical networks. The addition of the random noise throughout the system of prior weakened connections simulated the Pavlov/Luria so-called paradoxical phase of lexical selection whereby a picture of a cow elicited a "weaker" connected element (calf) that the stronger element (cow). of low frequency words. Recall that Harley and MacAndrew (1992) found the paradoxical effect (simulated it) only when they added random variation ('noise') by a distributed lessening of weights, "… into the weakened weight connections of the semantic to lexical levels." More recently, there is a follow-up on Marshall et al. by Hoffman et al. (2011), where again the semantic component was implicated as the location of the breakdown. They hypothesized that in an altered semantic system, the low-frequency words are much more prone to be perseverated and thus appear to stick in the production program longer than high-frequency words. These authors cleverly tested their patients on 'delayed repetition.' They found a significant advantage for precisely the low frequency, and this they correlated with the perseverative rate of those low-frequency words. This gave rise to the oft observed production of a low-frequency word substituting for a higher frequency in the semantic field on repetition. This would be a plausible explanation for the otherwise paradoxical reversal of expected frequency effects, which is what Pavlov found. It appears that Pavlov as a behaviorist described the physiological phenomenon correlated with the behaviors, but he did not go after any underlying cognitive processing account. Harley and MacAndrew in their connectionist 'lesioning' had weakened weight connections between the semantic and whole word lexical levels in their system, while subsequently adding some random 'noise' (random distribution of further weakening to the already weakened connections) in the same domain (semantic to lexical level). Harley and MacAndrew's simulations are at the very least intriguing. More awaits this intriguing reversal of Pavlovian rules of force.

The Connectionist Model of Gary Dell

In early work by Dell (1986) and Dell et al. (1997a,b) his model is introduced to a wide audience of aphasiologists – theoretical and clinical. Along the way, this model has been evaluated, assessed, criticized, praised with peer approbation, and further tested/expanded, by Dell and others (cf Martin, 2000; Martin and Dell, 2004, 2007). The model has IA architecture as seen in **Figure 6**.

Figure 6 From Martin, N., Dell, G.S., 2007. Common mechanisms underlying perseverative and non-perseverative sound and word substitutions. Aphasiology 21, 1002–1017. Special issue on Verbal Perseveration. In: Stark, J.A. (Ed.), Aphasiology. vol. 21, no. 10/11, Oct/Nov 2007.

As with Harley and MacAndrew's model, Dell does not invoke Hebbian Learning, but rather fixes the connection weight values in assuring that each input (the 'jolt' that gets the system operating) will normally be matched with its output match; word X in, word X out, with the heaviest weight total being the most activated, Dell's system in its initial crafting will simulate nonpathological productions by and large. He can then attempt to simulate the slips-of-the-tongue (of English), which of course constituted the elements and patterns he used in the first place, abiding thusly with the 'continuity thesis' we discussed above – the *sine qua non* of connectionist systems, Hebbian or not. **Figure 6** reveals four levels, with very little now to say specifically about the best way to structure the conceptual levels except to claim that semantic fields and notional categories would be conceived here: animals, furniture, sports items, foods, clothing, and on and on. Each of these would have sets of features, which are referred to as 'semantic features.' Our figure implies that we are treating the conceptual category of 'animal,' whatever that might turn out to be. Evidently, here we have a subset of features that would separate out the human animal – an animal nevertheless. At the lexical level, we can clearly see that the target (to be read aloud, repeated, or named, for example) is 'cat.' Heaviness of print is meant to relate to heaviness of weights – that would produce 'cat' in its semantic sense. Garrett would say that this word comes at the first lexical lookup. The system's weight values set by the builders themselves are first set for the normal case. Lookup 1 worked. This level then spreads downward through the heaviest weighted connection paths, which activate the three phonemes /k/ /ae/, and /t/. Then notice that there are feedback routes that interact with the word level, which itself has two way connectivity with the defining features. The architecture further shows that 'rat' is related to 'cat' by virtue of its shared semantic features, and it clearly shows another word 'mat' that only shares phonemic features – the so-called rime /-aet/. Then, we have the word 'dog,' which shares nothing phonologically, but surely shares some of the semantic features that 'cat' has – though not all, obviously. The architecture therefore 'knows' all the above facts on 'similarity' – either semantic or phonological, and the architecture can be sculpted in order to even favor words like 'rat,' since it associates with 'cat' both semantically and phonologically. Garrett called this the 'lexical effect,' which accrues when LL 1 and 2 interact. Dell works with interaction activation and Garrett's serial model can at least 'talk about' this in terms of the two lexical selections. Within reason, the two architectures can still talk to one another, although we know that the connections are far ahead of the game since they can work the interactions of a mathematical continuum, which squares better with continua of frequency of occurrence, how similar or not the items associated are and ultimately manipulating one and the same system to simulate health or sickness, as we have often shown how this all exists on a health-disease continuum for human language. Again, Dell, et al. (1997) spell out this *sine qua non*, as did Charcot, Hughlings-Jackson, and Sigmund Freud (Buckingham (1999). The beauty of this model is that it is at once localistic and holistic. The massive interaction is qualitatively distinct from its ability to reveal what is going on and where. The system can then be fixed in different ways to answer both theoretical questions as well as more practical clinical questions.

It was this feature that allowed Dell and Martin to be able to dissociate anticipatory versus carryover transpositions. They took the 'continuity thesis' and asked, if normal slips-of-the-tongue are for the most part anticipatory in nature, can we see this dissociation unfold in our model by altering it in ways we predict might be appropriate. Leaving the weights alone and allowing each activated element to return to its 'resting' level, i.e., the normal case, should if we run it too fast, or lower some weight values at distributed locations, or use low-frequency words, perhaps we could get the system to produce more anticipatory errors. If on the other hand, if we weaken the connections from word selection #1 to word selection #2, and also changes the rates at which activated items return to where they came from, we might see more carryover orderings. We do, and in so doing Dell has captured an anticipatory/perseverative ratio that will favor perseverations the more severe the lesioning is to select a word for reading, for repetition or more importantly, for naming. Further and simulating recovery processing, the Dell model can show, by slowly raising the weight values, the perseveration errors tend to wane, as the 'anticipatory ratio' increases. To the extent (but recall the Eaton et al. study) we see improvement run at least in tandem with the reduction of perseveration. This meets the dictates of the continuity thesis, since we are observing the subject approach normality, since the normal slip-of-the-tongue data reveal more anticipatory errors than perseverative. It can serve as a kind of clinical metric for charting the evolution of severe phonemic paraphasia or even the evolution of neologistic jargonaphasia. The evidence we have so far for the success of continuity thesis predictions will now force us to seriously consider findings such as those of Eaton et al. (2011).

Dell's model directly incorporates much of the localistic node symbology, which is later called up first for 'lesioning' the system and then for being able focus upon the exact region and elements that are causal, in that the weight alterations importantly cause the error – or so it can be made to seem. Although only focusing upon Hebbian Learning connectionist models as those of Paul Smolensky (1988), Ramsey et al. (1991) argue that no symbolic sense can be made in terms of what in that system play any causal role at all in the output forms, since the internal processing between input and output are opaque and chaotic. Correct outputs can be obtained although one cannot 'get at' the locations of causes for this or that error in an output, because these models are complexly distributed through the system, more on a 'mass action' analogy that is redundantly equipotential. This architecture for memory systems is not unlike what Lashley (1951) had in mind. The reader of this article would do well to read the Ramsey et al. (1991), which argues that the 'nonsymbolic' nature inherently structured in such self-organizing dynamic systems. There is a full historical account of this exciting era in Bechtel and Abrahamsen (1991), which according to some is, "… a less technical and more prosy introduction," Goldsmith (1993, p. 19, ftn. 5). Suffice it to say here that neither Harley nor MacAndrews's nor Dell's models suffer from these deeply recondite and nonsymbolic infelicities.

And, since their systems do not learn on their own, the weights must set by the architects of the architecture itself.

For Jerry Fodor and Zenon Pylyshyn (1988) and Stephen Stich (Ramsey et al., 1991) the symbolic and localistic models like Dell's at least stand a chance with challenges from symbolic representation theories of the mind and what is often called folk psychology,' folksy, since it is almost parochial to insist on theories of language that have the cognitive labels of human language, with elements that can be recombined in different ways and upon models where we can glimpse what is doing what, causing what, and where it takes place in the architecture. Needless to say, the proposals, the criticisms, and the counter-arguments are legion and not without deep mathematical, logical, philosophical, computational and linguistic complexities, and puzzles. The literature on this is not for the weak at heart. Our final assessment here is that the Dell model and others such as those of Trevor Harley have contributed so much to theory and to its clinical utility in the language and speech sciences they deserve to be further pushed for what is has said and what it can predict. We would also point out that the transparency between the processing architecture of Dell and Garrett is such that we have been able to transform from the serial to the connectionist in some meaningful way, even though connectionism in general has replaced the serial.

Brief Summary with Some More Anatomy

We want to make one thing very clear in our article on phonological disorders. Not only do functional models, psychological or linguistic, determine the underpinnings of how we describe and explain these disorders, but it has now become clear that anatomical modeling adds to the mix. We have seen that connectionist models can uniquely and localistically 'lesion' weights between the semantic levels and the lexical levels of their model, thereby producing many types of whole-word errors, but the alterations at this level only affect whole-word level phenomenon; they do not produce phonemic paraphasia. The 'anomias' are located here, presumably. The connectionist models can do the same, but within the level that maps fully selected, whole words onto their phonological forms. 'Lesions' here will neither simulate anomias nor semantic whole-word substitutions; they will simulate phonological disorders in terms of scrambling or otherwise derailing the phonemic structure of words, and that weakened weight 'lesioning' causes scrambling and derailing within the mapping between the lexical level and the phonemic (sublexical) level. This traditional way of thinking challenges the so-called 'anomia' theory of neology (Buckingham, 1977), Butterworth (1979), Buckingham (1981), and Buckingham and Christman (2008), and appears to allow it no possible second role in explanations of neologistic jargon aphasia. That in turn infiltrates how we view the very nature of neologistic production, and thus it colors our views of a great deal of phonological disturbances.

Furthermore and very importantly, there are anatomical accounts of brain regions and their connections that also, and often as a consequence of, duplicate many connectionist accounts of neology, anomia, semantic, and phonemic paraphasias. In Buckingham and Christman (2008), we assessed the model proposed and utilized in Hillis et al. (1999) for jargon aphasia. The single patient used was an adult with conduction aphasia whose principal disruption was phonological activation, which of course implicates the phonological system as the location of the breakdown. The subject could read passively, match words with pictures, understand and speak with fluency, whereby the authors assume that full connectivity between the semantic and the lexical levels remained uncompromised. They then proceeded to 'lesion' their connectionist system between the lexical and the phonemic level of representation (the 'sublexical level'). They left the decay rate weights alone and did not alter any weights in the semantic to lexical mapping. Their simulations indeed showed phonemic paraphasias and neologisms on oral naming, repetition, and oral reading testing. Anatomically, the patient had brain damage that interfered with the white fiber tracts mediating information exchange between the posterior, superior temporal gyrus in *dorsal* BA area 22 and the more *ventral* regions of BA 22. Crucially, then they propose that dorsal 22 is a site of the phonological processing of words (already correctly selected) and that ventral 22 is 'likely' to be an area for the representation and processing of whole-word forms. It therefore is evident that this study supports 'the conduction theory' of neology, eschewing 'the anomia theory.' All connectionist studies, according to these authors, have simulated neology lesioning the lexical to sublexical levels and that some have globally lesioned their systems and again observed neology. We are not told if those studies saw any difference in degree of severity of the segmental paraphasias that were nonword and unrecognizable. We also do not find out if there was any evidence with the global lesioning simulations. Hillis et al., however, globally lesioned their connectionist system but, alas, could not simulate neology. Consequently, their schema would not allow for or include an 'anomia theory' of neology. Currently, however, there has been increased appreciation of the more ventral regions in the left temporal lobe, in addition to the more classical position for phonological processing in the dorsal regions of Wernicke's area, the Ptp and the supramarginal gyrus (Area 40), processing whole word lexical/semantic functioning the line of recent work on not only classical aphasiology's dorsal system, but now has recognized lexical/semantic processing in the ventral regions in addition to the more phonological processing in dorsal regions.

At the present, the technology of magnetic resonance imaging has led to the even more interesting and revealing diffusion tensor imaging, whereby the biochemical structure of water and its hydrogen atoms react under magnetic conditions to 'line up,' and since the imaging is on fiber tracts and not cortex, the lined up structure highlights, often quite beautifully the actual fiber tract. This technology has opened up impressive studies of already known fiber tracts, plus much that we have not been able to observe. We've seen new tracts, and extensions of tracts, and coursings not yet completely understood.

The focus on ventral function actually started with Hickok and Poeppel (e.g., 2004, 2007) and now with DTI has progressed further with the ventral tract and its extensions from occipital zones (the inferior fronto-occipital fasciculus, lower down and coursing through the external capsule and the extreme capsule, terminating in BA 45 (the pars triangularis).

This anatomical work often brings out functional connectivity differences between BA 44 and 45, often simply considered as a whole as Broca's area; others, though are more careful to constrain the IFG to 44. In even more recent work, the excitement continues with studies such as Friederici (2009) and even more recent ones by Brauer et al. (2013). The point to all this is that, as we saw with the Hillis et al. study, these recent investigations of the ventral regions in the left hemisphere could also color our descriptions of phonological disruptions and systems that might be able to compensate or help ameliorate phonological disorders. These ventral regions have also played a role at the semantic level, as have other ventral areas in posterior middle temporal lobe on the left at the location of the fusiform gyrus that connects with anterior occipital regions. Lesions in this region often gave rise to the production of semantic, whole-word substitutions (either paradigmatically or syntagmatically related in Jakobson's terms, which of course originated in Aristotelian theories of association). There were no sublexical errors found in these patients.

In the end, and as we proposed at the outset of our article, suffice it to say that as neurolinguistic modeling goes, so goes the way we ultimately understand the complex nature of phonological disorders. Here, we would suggest that more work needs to be done on the fluent paraphasias of patients who sustain somewhat larger brain lesions that encompass both ventral and dorsal in the posterior regions of the dominant hemisphere. The paraphasic composition of this group of patients needs close scrutiny.

Future Directions

Most obvious to watch for in future studies of phonological disorders will be further connectionist modeling with close attention to neuroanatomical innovations from imaging technology. We also look for further work in the phonology from OT (McCarthy, 2004) and harmonic phonology (Goldsmith, 1993). These two programs need some disentanglement (see McCarthy, 2004, p. 6), however, since both seem to harmonize in distinct ways. Presumably, OT is being worked out as an exercise in setting up a competence of sorts for Smolensky's connectionism, as we briefly discussed earlier in this article. We are not aware as yet of much language simulation of normality and pathology from these subsymbolic, Hebbian Learning models. Goldsmith's (1993) harmonic phonology has accomplished the simulation of sonority constraints and Turkish vowel-harmony, but certainly not with a subsymbolic connectionism. However, we are not aware of any work in aphasia by him, and only brief connectionist work by Wheeler and Touretzky (e.g., (1997), which we discussed earlier in the article, where they simulated much of the findings on phonemic paraphasia and neology of the work by Buckingham (1986, 1987, 1989, 1991). OT carves out much more complexity in phonotactic constraints. For example, in mapping out sonority constraints, OT would claim that sonority rests not on a general hierarchical degree of "level-true "goodness," such as the focus on overall statements such as that OV's (Obstruent-Vowel) are preferred to NV's (Nasal-Vowel), which are preferred to LV's (Liquid-Vowel), which are preferred to GV's (Glide-Vowel). What has heretofore been left out of the equation is the fact that sonority can only make real sense as it combines with the variant analyses of how the segmental arrays or syllable constituents remain 'faithful' to the extent that their underlying input forms match precisely their output forms. It is no longer strikingly crucial to simply claim that the English word 'quite' abides less by a goodness of sonority fit than the English word 'cry,' since the segment order /kw+V/ is less preferred than the /kr+V/. Otherwise we would be obliged to claim that /kway/ would be a more preferred pronunciation for 'cry.' OT claims that this type of phonotactic statement is 'parochial' (McCarthy, 2004, p. 6). Other phonologists such as Diana Archangeli have called it 'trite.' Repair strategies show this. What if, for whatever reason, the word 'quiet' is uttered as /kayət/? If the repair strategy were based on sonority preference, why would the repair to correctly utter 'quiet' select a 'less preferred' sonority choice kw+V over k+V? To match input to output for 'quiet' one would have to select the less-preferred sonority ranking segment string. In any event, we await future studies in aphasia simulation from systems such as Goldsmith's or Smolensky's. To date, however, it seems that the Dell model has the big lead in the study of paraphasia in brain damaged adults with fluent phonological disorders.

Abstract

Articulatory phonetics is concerned with consonants and vowels (segments) as well as tone and phonation types (phonationals). For more than a century, it has been deemed as an applied discipline for practical purposes such as language teaching and description. In recent years, articulatory or linguistic phonetics has developed quickly and general theories are attempted to organize various concepts into a consistent system to account for phonetic phenomena. This article introduces a syllable-centric phonetic theory, which treats tone and phonation types as nonlinear syllabic constituents and consonants and vowels as linear constituents. Phonetic typology is also explored in the article.

Introduction

Phonetics, in its earliest sense, means articulatory phonetics. Although it has now developed into a greater 'phonetic science,' containing dozens of interdisciplines, its base or core part is still articulatory phonetics.

'Articulation' has two meanings. In the narrower sense, it refers to the movements of articulators in the oral tract that produce 'segments' (vowels and consonants). In the broader sense, it also includes 'phonation,' the laryngeal or vocal fold activities, to produce 'suprasegmentals' (cf Suprasegmentals in this volume) or 'phonationals' (register, pitch, and length). Since segments are the main subject to study in traditional phonetics and suprasegmentals are merely secondary features, the two meanings do not create much ambiguity.

In this article 'articulation' (and 'articulator' as well) is used in the narrower sense, as opposed to 'phonation.' However, 'articulatory phonetics' is used in the broader sense, covering the study of both articulation and phonation. It is concerned with the production of speech sounds (cf Speech Production, Psychology of and Speech Production, Neural Basis of): how the vocal cords modify the airstream, when it passes through, to bring about different 'voice qualities' and how the articulators further modify the airstream coming out of the glottis to form different 'sound qualities.'

The interest in the exploration of speech sounds started as early as two thousand years ago in ancient India and ancient Greece, and later in ancient Arab. In ancient China, phonetics emerged in the first century CE (*fanqie* spelling), continued progressing in the sixth century (rhyming books), and flourished around the tenth century (classification of consonants and rhyming tables). Modern phonetics emerged in the late nineteenth century marked with a series of academic events, one of which was the design and promulgation of a set of phonetic symbols, the International Phonetic Alphabet (IPA), by the newly established International Phonetics Association as a standardized representation of all the speech sounds in human languages.

For more than a century phonetics has been deemed as an applied discipline for such practical purposes as language learning and teaching, dictionary making, language/dialect description (cf Dialectology in this volume), speech pathology, singing and acting, translation, and spelling reforms (cf Writing Systems in this volume). Its main task is to describe and classify segments, with suprasegmentals as its subsidiary task.

Since the late 1970s articulatory phonetics has developed quickly in the studies of consonants, vowels, phonation, and general theories.

A great number of new consonants were found and identified, which resulted in a total of five revisions of the IPA chart in a quarter of a century (1978–2005). In the earlier half a century only one revision was made in 1952.

The nature of vowels has been reconsidered. Vowels were previously defined with respect to two physiological criteria: (1) they have a wide enough oral track for the outward airstream so that no noise would be generated, and (2) they are described along three physiological parameters: height (or mouth openness) and backness of the tongue position, and lip rounding. These criteria have been replaced by two new ones. First, the vowel space is defined by the acoustic dimensions of the first two formant frequencies. Second, the nature of the vowel is understood with reference to its phonological status in a syllable.

A new subject, phonation modes, attracted extensive studies first in physiology and acoustics, and later in linguistic phonetics. There are as many as two dozen phonation types in terms of physiology (Catford, 1977; Laver, 1980). In linguistic phonetics, however, only six were identified (Ladefoged and Maddieson, 1996). Recently, in the light of tonal typology and sound evolution, a phonological system of phonation types has been established (Zhu, 2011a), which contains 14 types, grouped into six major types. This finding has amended the classification of consonants, brought about a new tonal model, restructured the syllable, and eventually reshaped the overall phonetic framework.

The most important change happening in phonetics is the change in theoretical conception in recent years when 'linguistic phonetics' (Ladefoged, 1971) is becoming matured. In his linguistic phonetics Ladefoged (2006) conceptualized an overall theoretical framework, in which phonetics was absent. Zhu (2008, 2011a) attempted to refine the framework by setting the syllable as the basic and pivot unit. These theoretical studies have improved the understanding of phonetics.

The remaining part of this article will address some theoretical issues in phonetics before introducing criteria for segment

description and classification, followed by a system of phonation types and a set of parameters for tonal representation.

Theoretical Considerations

Linguistic Phonetics Being Phonology

'Pure' phonetics was largely separated from linguistics long ago. Phonologists, from early years' structuralists to the present generativists, include only phonology in linguistics and regard phonetics as part of physics (e.g., Trubetzkoy, 1939; Anderson, 1981). As 'functional phonetics' (Martinet, 1949), "phonology begins where phonetics leaves off" (Sommerstein, 1977; cf Phonology in this volume). Enormous changes have taken place in the past few decades. Phonetics has now become such a large field that it contains dozens of interdisciplines. The phonetics that linguists pursue is what Ladefoged called 'linguistic phonetics,' an interdiscipline of phonetics and linguistics. It developed from articulatory phonetics and remains the core part of the greater phonetic science. As a phonetic discipline, it differs from other disciplines such as engineering phonetics, forensic phonetics, and pathological phonetics in that it is of linguistics, by linguistics, and for linguistics. When facing various linguistic disciplines, however, 'linguistic phonetics' is not an appropriate term because there are no such terms as 'linguistic syntax' or 'linguistic morphology.' In linguistics, 'linguistic phonetics' is just phonology, or the core part of phonology. That is why basic phonetic concepts such as the consonant and vowel should and can be defined with reference to their phonological roles in a syllable, in addition to their articulatory and acoustic criteria and why phonology should and can be conducted based on phonetics.

Basic Framework

There is no explicit general phonetic framework before Ladefoged's proposal. The traditional consensus in phonetics is that the segment is the core subject to study, with suprasegmentals (pitch and length) as secondary features, as schematically represented in Figure 1(a). Ladefoged's framework (Figure 1(b)) is like a diagrammatic combination of the traditional common view and the three processes of speech production (Catford, 1977): initiation (=airstream), phonation (=laryngeal), and articulation (=supralaryngeal).

The segment-centric view has been the mainstream view in phonetics. Yet there is another view held by British linguists (e.g., Abercrombie, 1967) which sets the syllable as the basic unit. This is also a millennia-long tradition in Chinese phonetics/phonology. Following this thread, a new linguistic phonetic framework has been developed (Figure 2).

A syllable has two kinds of components, the linear segments and the nonlinear phonationals. They can be phonologically organized to form linear onset and rime as well as nonlinear register, length, and pitch.

Segments

Segments include consonants and vowels, which, during production, involve (near-) closing and opening of the vocal tract. The most widely used symbols for notating segments are the IPA, which is presented in Figure 3.

Consonants

'Normal' consonants are produced with an egressive airstream. They are arranged in the pulmonic consonant table at the top of the IPA chart (Figure 3) along two dimensions: place and manner of articulation. Places of articulation, also called articulatory targets or passive articulators, refer to the locations in the upper and back areas in the vocal tract where active articulators (the lower lip or the tongue) approach to form various kinds of constrictions to impede airflow. Eleven places of articulation, e.g., labial, alveolar, etc., are established in the table. They are listed on the right side of Figure 4 except one, retroflex, which refers to a type of consonant involving an articulatory target somewhere between postalveolar and palatal and an active articulator of subapical or the tip of the tongue. Note that, according to Jakobson et al. (1952), the 'glottal' sounds

are neither consonants nor vowels. Rather, they are phonation types (cf section 'A System of Phonationals' in this article). Active articulators refer to the lower lip and various parts of the tongue, whose terms are given in the middle of the figure. Along the left side are hyphenated terms of active articulators, which, when combining with those for place, form terms of articulatory gesture, e.g., bilabial (labio-labial), labio-dental, apical-alveolar, lamino-dental, etc.

'Manner of articulation' refers to the methods of maneuvering the airstream during consonant production. The airstream can, when going through the vocal tract, be totally blocked before being released (plosives or affricates) or near blocked (fricatives), make little noise (central and lateral approximants), or go out of the nostril (nasals) instead of the mouth. There are two other terms, 'rhotic' and 'liquid,' which are fairly common but not established on the IPA chart. The

Figure 4 Places of articulation.

former refers to seven *r*-sounds, which could be trills, taps/flaps, or approximants. The latter is a cover term for laterals and rhotics.

In the consonant table there is a third dimension, voicing, implied in the presence of pairs of symbols for obstruents (plosives and fricatives) such as [p ~ b] and [s ~ z]. For example, the symbol at the right, i.e., [b], indicates a voiced sound, and that at the left, [p], voiceless, with the status of aspiration (and breath, etc.) unspecified. This kind of presentation results from the practical and convenience purpose of using the existing Latin alphabet, whose basic function is to transcribe speech sounds in European languages. There are also voicing contrasts occurring in sonorants such as [m · ~m], [n · ~n], and [l · ~l] in other languages but not presented in the table due to the lack of Latin letters. Moreover, the contrast between voiceless and voiced involves only two types of phonation modes; so far up to 14 phonation types have been identified in linguistic phonetics. It is, therefore, better to represent all the contrastive phonation types separately (cf section 'A System of Phonationals').

In the newer versions (1989 onward) of the IPA a nonpulmonic consonant table is included, which contains clicks, implosives, and ejectives. The latter two can also be treated as phonationals because their production and the phonological features that distinguish them from other plosives at the same place of articulation involve glottis movements rather than articulatory gesture.

There is also a list of 'other symbols' on the IPA chart which contains consonants with double articulations of place/manner ([ʍ, w, ɥ, ɰ], etc.) and three rarely seen epiglottal sounds [ʔ, ʕ, ʜ]. Only the pair of prepalatal or alveolo-palatal fricatives [ɕ, ʑ] is an exception. Prepalatals are commonly used in Asian languages such as Sinitic, Tibeto-Burman, Hmong-Mien (Miao-Yao), and Tai-Kadai but rarely seen in European languages (with Polish as an exception). They were previously placed in the consonant table (the 1978 version) next to the palato-alveolar [ʃ, ʒ] (now 'postalveolars'). The two sets of sounds share a similar place of articulation and usually do not contrast with each other phonemically; these might be the reasons to remove the prepalatals out of the consonant table in the later IPA versions. There is, however, an auditory distinction between the two, and a constant articulatory difference is that [ɕ] is more palatalized whereas [ʃ] is more labialized. Perceptually, to a Westerner's ear, Mandarin's [ʂ] rather than [ɕ] sounds more like English's [ʃ]. On the other hand, Mandarin speakers would say [tʂʰɜtʂʰ] rather than [tɕʰɜtɕʰ] when learning to speak the English word 'church.' Even for professional Chinese dialectologists, Cantonese obstruents at that place of articulation are transcribed as [ʧ, ʃ], meaning they are distinguishable from Mandarin [tɕ, ɕ] and sound more similar to those in English.

Vowels

Vowels are placed on a chart according to the positions of the tongue: high–low (or close–open of the mouth) and front–back. When the high-front vowel [i] is being produced, the blade of the tongue is forwarded to approach the alveolo-palatal region. When [u] is being produced, the 'bunched' tongue is pulled back to get close to the velum. While almost all languages in the world have these two high vowels and a low vowel /a/, some have both front [a] and back [ɑ]. There is also a third dimension on the chart: paired symbols like [i ~ y] are distinguished by the shape of the lips, with the symbol on the right indicating a rounded vowel.

The vowel chart defines a physiological quadrilateral space for vowels to reside in. This physiological criterion for vowel description has been changed to an acoustic one. In the newest edition of the *Handbook of the IPA* (1999), the vowel chart in a language is drawn along acoustic parameters of the first two formants' frequencies. For example, the front vowel symbol [ɪ], physiologically defined as between [i] and [e], is placed 'correctly' in the Hindi chart (p. 102), but as low as [e] in the German chart (p. 87) and even lower than [e] in the American English chart (p. 42). That is, a vowel now has its absolute values in terms of formant frequencies, so the IPA phonetic notations share about the same nature as phonemic representations.

In addition, new understanding of the nature of the vowel arose that the vowel is not a solely phonetic concept, but is defined with reference to phonology. This view is reflected in the *IPA Handbook* (1999), in which vowels are defined as "sounds which occur at syllable centers, and … involve a less extreme narrowing of the vocal tract than consonants" (p. 10). Or, more straightforwardly, "the vowel is produced without apparent constriction along the oral tract and serves as the syllabic component of *nucleus*" (Zhu, 2010, p. 231).

Secondary Features

Secondary features are represented by symbols in the 'diacritic' table and the lists of suprasegmentals and tones in the lower part of the IPA chart. Most of the diacritics are used to indicate minor adjustments of articulation. The two for 'syllabic' and 'nonsyllabic' are phonological notations. The remaining five in the top-left corner of the table, voiceless, voiced, aspirated, breathy voiced, and creaky voiced, are symbols for phonation types, which are better grouped with tones and suprasegmentals as phonationals.

Phonationals

A System of Phonationals

Phonationals are divided into three groups: phonation types (cf Phonation Types in this volume), major types, and supra-phonationals, which are listed in Table 1.

Traditional phonetics usually deals with three COMMON phonation types: voiceless unaspirated, voiceless aspirated, and modal voice. Ladefoged considered three more (breathy voice, creaky voice, and glottal stop) and regarded all the six as properties of stop consonants. Phonation types are actually equally realized on fricatives, sonorants, and even more on nuclear vowels; they are properties of the syllable rather than of a single segment.

Supraphonationals include length and pitch. Length is subcategorized into long, mid-short, and short, according to the tonal behaviors in Cantonese and other tone languages. Pitch will be discussed in detail later.

Composition of Phonational

Phonational (‘Ph’ in Figure 5), as the first-level nonlinear syllabic constituent, can also be named *tone* (T). Tone consists of three components: *register* (Rg), *length* (Leng), and *pitch* (P); pitch is comprised of *height* (Ht) and *contour* (Cnt). Tone is, therefore, described and represented along four parameters: register, length, height, and contour. These parameters can be subcategorized. *Register*, *length*, and *height* all show a tripartition contrast, i.e., *register* U, M, and L, *length* long, mid, and short, and *pitch height* in 2-way, 3-degree, and 4-level contrasts. Pitch *contour* can be categorized as *level*, *rising*, *falling*, *dipping*, and the less known but rather frequent type *pure low tone*, a low tone without CONTOURICITY specification (Zhu, 2012b). These components are hierarchically structured under the syllable as in Figure 5.

Phonologically, *register*, *length*, and *pitch* are associated with *phonational* or *tone*. Phonetically, “the tone features are sometimes relevant for the initial consonant, sometimes for the nuclear vowel, and sometimes for the final consonants” (Wang, 1967). *Pitch* and *length* are shown on *rime*, and *register* can be on either *onset* or *rime*.

After the nonlinear components have been defined, it is not important which component, the Ph, P, or Cnt, is called ‘tone.’ Or, they could be called ‘tone$_1$,’ ‘tone$_2$,’ and ‘tone$_3$,’ respectively. In the syllable theory (Zhu, 2008), as shown in Figure 5, ‘tone’ equates to *phonational*, dominating all other nonlinear components.

Pitch can be contrastive by height only or by both height and contour. The 2-way contrast in pitch height refers to stress and the accentual tone in Japanese, the 3-degree one to the African register tone and 3-degree stress, and the 4-level one to the Asian contour tone.

In nontonal languages, laryngeal activities are less active and therefore the phonational tier could be saved in their linguistic–phonetic representations. With regard to a few COMMON phonationals such as the two degrees of pitch (strong vs weak), length (long vs short), and phonation (voiceless vs

voiced) in these languages, they can be treated, for the sake of convenience, as secondary features of consonants (voicing) or vowels, i.e., suprasegmentals (stress and length). In tone languages, on the contrary, there are more phonationals, usually LESS-COMMON, in the nonlinear tier.

Contour tone is by and large in complementary distribution with stress. In a typical tone language such as Cantonese there is no room for stress, because (1) the language is monosyllabically morphemic and stress resides on polysyllabic words and (2) pitch, the main phonetic cue for stress in nontonal languages, is fully utilized for the distinction of tone in tone languages.

Registers Realized as Phonation Types

The six major types are arranged from top to bottom in Figure 6 roughly in accordance with pitch height. By these phonation types three tonological registers are defined. Not every phonation type can identify a register. Essentially, only three types, falsetto, clear-1, and breathy voice, if occurring in a tone language, can define an independent register. Falsetto defines the highest Upper Register. Breathy voice defines the lowest Lower Register. Clear-1 defines the commonest, default, Modal Register. Every tone language, every language indeed, has this register.

Figure 7 shows the statuses of vocal cords of three phonation types. The vocal cords in the left panel, which is for a falsetto sound, are stretched tightly; they are longer, wider, and thinner than the ones in the middle panel, which is for a modal voice. In the right panel is a slack voice. The vocal cords in this panel do not close entirely. Airflow is continuously leaking out through the aperture of the glottis even during the closing phase of vibration. Slack voice is perceived as having a low pitch and noise on the vowel.

The clear-2 (modal) voice usually does not define a phonological register alone; it is ordinarily accompanied by one or another nonclear voice. For instance, modal voice co-occurs with slack voice in Hmong, Wa, Wu, Xiang, and Gan, and with creaky voice in Thai, Hani, Lolo, and Lahu, etc.

Creaky voice is the commonest among the members of stiff voice. It is associated with the lowest human pitch, and will cause a 'broken tone' in terms of both acoustics and perception. In addition to contrasting with other phonation types in nontonal languages like Mon-Khmer, creak is also found in hundreds of varieties of Chinese and other tonal languages such as Vietnamese and Yi (Lolo). In most tonal cases, creak is a phonetic realization of either M or L Register, serving as an accompanying feature of a low tone. Only in a few linguistic varieties is creak found to play a role of distinctive feature in differentiating two otherwise identical tones (Mai, 2007; Zhu and Yang, 2010). In this case, stiff voice alone defines an L Register.

The last one, fortis voice, is rather subtle in terms of physiological characteristics and acoustic manifestations. Note that fortis and stiff voice are different from the 'stiff voice' suggested by Ladefoged and Maddieson (1996). In short, fortis voice is associated with fortis/strong/long/tense voiceless consonants, e.g., Korean fortis stops and Wu preglottalized consonants, which induce a higher pitch and larger intensity on the following vowel than nonfortis voiceless consonants do. Fortis voice is usually a variant of falsetto or clear-1 and seldom defines a register itself.

Phonation types are not consonants' properties; they define registers, which constitute a syllabic component. Two of them, clear-1 and clear-2, are normal clear voices or COMMON PHONATIONALS and acoustically realized on the initial consonant as well as on the nuclear vowel (a higher pitch after a voiceless than after a model voiced consonant); three, falsetto, slack, and stiff, are nonclear voices or LESS-COMMON PHONATIONALS and are realized on vowels and occasionally on consonants. As for fortis voice, two of its varieties, pre- and final-glottalization, are COMMON PHONATIONALS, and the other two, implosive and ejective, are LESS-COMMON PHONATIONALS. That Register M is defined by clear-1 means Register M is a property of the syllable that begins with an *onset* in clear voice: either a voiceless obstruent, a normal sonorant, or zero *onset* in a clear-voiced syllable.

Multiregisters and Four-Level Tonal Model

Based on the syllable model (Figure 5) and the mapping of phonation types onto registers (Figure 6), a new tonal model, the Multi-Register and Four-Level tonal model, is developed (Zhu, 2012a). Basically, it is suggested that (1) a language may have more than one type of phonation which defines up to three tonological registers; (2) each register has its own pitch range, which is divided into four levels; and (3) each register is one notch lower/higher in pitch than an adjacent one. Figure 8 shows a total of three registers and six pitch levels).

In this model the four Beijingese tones are all piled in Register M and numerically transcribed as {55, 35, 22, 52}, and the seven Thai tones, five long and two short, reside in Rg M, too: {33, 22, 52, 45, 25, 45, 32}. Of the six long and two short Vietnamese tones, one is in Rg U, {405}, five in Rg M, {44, 33, 35, 55, 33}, and two in Rg L, {202, 40}.

Phonational Typology

While data of segment distribution (Maddieson, 2005) have been accumulated to an extent that typological studies can be carried out (cf 52009 in this volume), those of phonationals still lack.

Exploration of tone typology started decades ago (Wang, 1967; Cheng, 1973; Maddieson, 1978), based on impressionistically descriptive data. It did not flourish until recently when sufficient amounts of acoustic data were accumulated and a phonational model proposed (Figure 5). There are five basic contour types: level, falling, rising, dipping, and the pure low tone. The falling tone has 11 subtypes (Zhu, 2012b), and the dipping tone, seven (Zhu et al., 2012a). The level tone is the most distinctive one and may have up to six distinct heights (Zhu et al., 2012b). The falling tone is the most frequent type in tone languages. A typological statement can be stated as 'if there is a tone in a language, it tends to be a falling one,' or in terms of implicational universal, 'a level tone implies a falling tone.' Figure 9 shows a typical example from Chálíng Gàn , which has five tones: three circumflex and two falling but no level.

As a LESS-COMMON phonational, tone often does not occur in a language alone, rather it co-occurs with other LESS-COMMON phonationals. The following maps show the geographical coincidence between tones and implosives. Not accidentally breathy voice is also found in the same areas and falsetto in East and Southeast Asia (Zhu, 2010). Geographical locations seem to correlate with linguistic–phonetic patterns: the languages on warmer continents are more phonation-active, while those in colder regions are more segment-prominent

(with more complex phonotactics). A salient example is the Indic languages, which gained implosives and breathy voice after their migration from colder Europe to the warmer subcontinent (Figure 10).

Classification of Some Special Segments

There are some special or strange consonants and vowels whose phonetic properties were previously known to a certain extent but which are difficult to classify phonologically. They are now accountable in the phonational classification (Table 1). Moreover, phonetic properties previously thought to belong to consonant, vowel, or tone separately can be treated uniformly in light of the phonational system.

Three Sets of Voiceless Stops

There are three sets of voiceless stops in Korean, which have been a puzzle in phonetics and phonology for decades. While the aspirated one is considered 'normal,' the other two, unaspirated sets can only be labeled as 'fortis' and 'lenis,' transcribed as, say, **p* and *p* (see the Korean table in Table 2). While the lenis stops have a longer Voice Onset Time (up to 60 ms) than the fortis ones (usually below 30 ms), the perceptual and acoustic properties of the stops are mainly manifested on the nuclear vowels: weaker in intensity and lower in pitch for the vowel after the lenis consonant than for the vowel after the fortis. The problem is how to classify them phonologically or linguistic-phonetically. In terms of the phonational system, they can be classified as different phonation types (Zhu, 2011b): the fortis consonant (the *onset* of a fortis syllable indeed) is of Type 2 preglottalization (like that in French) with an allophonic variant unaspirated (Type 5), and the lenis consonant is of Type 7 weak aspiration with two variants: weak slack (Type 14) and modal voice (Type 8) (Table 2).

There are also three sets of stops in Wu Chinese (see the Wu table in Table 2): a normal aspirated p^h, a 'clear' *p*, and a 'murky' or 'voiced' *b*, as termed in Chinese phonetics and phonology. The murky set was eventually voiceless (Edkings, 1868), but with 'voiced aspiration' (Chao, 1928). In the phonational system the unaspirated *p* is classified as Type 2 preglottalization with an allophone of Type 5 unaspirated, and the murky *b* as Type 13 slack voice with a variant of

Type 8 and Type 14. This is also true for the Hmong language and Xiang and Gan Chinese. Note that there is also a distinction between 'clear' and 'murky' sonorants in Wu, so they are not just properties of stops.

In fact they are not even (syllable-initial) consonants' properties. The perceptual and acoustic properties of these special sounds are mainly manifested on the rime rather than on the onset. Moreover, there is a 'clear' and 'murky' distinction between syllables without initial consonants. It is, therefore, reasonable to assign the phonetic features of these sounds to the syllable rather than to a single segment.

Tense versus Lax Vowels

The distinction between the tense and lax vowels in English involves segment contrast, with a secondary contrast in length (and other physiological factors that are not phonologically categorized, e.g., wall resistance), but the tense/lax distinction in Austroasiatic and Tibeto-Burman languages involves phonation contrast.

In both Wa of Austroasiatic and Hani of Tibeto-Burman there are two sets of vowels, labeled as ‘tense’ and ‘lax.’ Their phonetic properties and phonological contrast, however, are totally different. In Wa the tense vowels are in normal clear voice while the lax vowels are in slack voice. In Hani, on the contrary, it is the lax vowels that are in clear voice and the tense vowels in creaky voice. So along the ‘tense/lax’ dimension, defined by the adductive tension and medial compression at the glottis, there are at least three values rather than two. As the Hani creaky voice also occurs on the initial consonant sometimes, and the Wa slack voice also affects the initial consonant and makes it ‘murky’ or ‘lenis,’ the phonation types occurring in these languages are not just vowels’ properties, but syllables’.

There has been a puzzle in Wa phonology on why the tense/lax vowel contrast only occurs after an unaspirated consonants. After an aspirated consonant, there are only tense vowels. This is just the case in Korean and Wu: the distinction between fortis/lenis or clear/murky only occurs in unaspirated consonants. So the phonetic nature of the Wa vowels is the same as that of the Korean and Wu consonants: they are all caused by (weak) slack voice (or weak aspiration) at the syllable level, but treated differently in different languages as vowels’ or consonants’ properties.

Moreover, the same slack voice can also be treated as a tonal property in tonal languages: *yang* tones in Wu and even numbered tones in Hmong. Since most of the Austroasiatic languages are nontonal, the slack voice is treated as vowels’ property. Wa is an Austroasiatic language that has four newly emerging tones, three for native words and one for words borrowed from Chinese.

In traditional phonetics and phonology, ‘fortis/lenis’ or ‘clear/murky’ are considered as consonant contrast, ‘tense/lax’ as vowel contrast, and ‘*yin/yang*’ or ‘odd/even numbered’ as tone contrast with unrevealed phonetic properties. They can be analyzed uniformly now in the system of phonation types.

Summary

Phonetics has expanded its territory quickly in the past few decades. Dozens of new disciplines have emerged. By interacting with them, articulatory phonetics has changed enormously so that a split of the discipline has taken place. Half of it remains as articulatory phonetics but is leaving from linguistics. It has become more technology oriented, and many efforts have been made in articulatory modeling, which is more like engineering phonetics than linguistic phonetics.

The other half remains in linguistics but is no longer pure articulatory; it resorts to more parameters than the articulatory parameter. This split is so significant for linguistics that it would reshape linguistic articulatory phonetics and affect disciplines such as phonology, typology, dialectology, and evolutionary/historical phonology. This linguistic articulatory phonetics is becoming more theoretically oriented. It is still part, maybe the core part, of the greater phonetic science, yet differs from other phonetic disciplines in that it is of linguistics, by linguistics, and for linguistics. So it is not ‘pure’ phonetics. In linguistic phonetics, physiological and acoustic parameters are sought after, but they should be phonologically conceptualizable or categorizable, or have linguistic implications for typology or phonological evolution.

Phonetics is to phonology what physics is to chemistry. In phonetics and physics, the basic unit is the smallest analytical element, while in phonology or chemistry, the whole study is established on a structural unit: syllable in phonology and molecule in chemistry. Had chemistry not had its own basic, structural unit, it would not have been independent or autonomous from physics. Phonetics overlapping with linguistics has given rise to the linguistic, articulatory phonetics, which, as part, maybe the core part, of phonology, has the syllable as its basic unit.

Abstract

Phonology deals with sound structure in language. While phonetics studies the physical properties of sounds, phonology concerns their mental representations. Phonology originated with the insight that much observable phonetic detail is irrelevant or predictable in language. This led to positing *phonemes* as minimal contrastive units, each comprising a collection of *distinctive features*. Later work went beyond this focus on surface contrast and re-conceived phonology as an aspect of speakers' mental grammars. Theoretical debates have involved the interaction of phonological regularities; the relation of phonology to other components of grammar; and the use of rules versus constraints to encode phonological regularities.

Phonology is concerned with the sound structure of words and utterances, the way distinctions in sound are used to differentiate linguistic items within a language, and the ways in which the sound structure of the 'same' element varies as a function of the other sounds in its context. While both phonology and phonetics are concerned with the role of sound in natural language, they differ in that phonetics deals with the articulatory, acoustic, and perceptual properties of sounds (*see* Phonetics, Articulatory), while phonology studies the ways in which these properties are represented in the mental grammar and how the grammar manipulates these representations.

Goals of Phonology

The study of a language's particular phonological system has a number of aspects. First, it must be able to characterize the language's *inventory*: which phonetically possible sound types occur in utterances in the language? Second, it must characterize matters of *contrast*: which of the phonetic differences that occur in the language can serve to distinguish utterances (words, sentences, etc.) from one another? Third is the matter of *contextual limitation*: even though some property P occurs in language L, are there some environments from which P is excluded? And when P is apparently a property of (some part of) some element but that element occurs in a position from which P is excluded, what other property – if any – appears in its place? Finally, and to some phonologists most importantly, there is the description of *alternation*: when the 'same' linguistic element appears in different overt forms in different environments, what systematic differences occur? What conditions govern the range of phonetically distinct forms that can count as the 'same' word, morpheme, etc.?

It should be noted that the present article is limited to the phonological systems of spoken languages and ignores manual or signed languages (*see* Sign Language). This is misleading in important respects; it has been argued that most of the basic principles of spoken language phonology characterize the organization of signed languages as well (Coulter, 1993). Just as words are composed of sounds, and sounds of component properties, signs are also composed of structured systems of more basic constituent elements. Units such as the syllable have close parallels in signed languages. While there are clear differences that depend on modality, these are argued to be relatively superficial. A comprehensive theory of phonology as a part of the structure of natural language should take these broader issues into account.

Some History

Prior to the early twentieth century, studies of sound in language concentrated on the ways in which sounds are made (articulatory phonetics), often confusing the letters of a language's writing system with its sounds. Toward the end of the nineteenth century, however, increasing sophistication of measurement techniques made it possible to explore a much wider range of differences among sounds, and to lay out the structure of speech in vastly greater detail. Much of what was found involved the observation that speech is continuous, such that whatever is going on at any particular moment is at least a little different from what has gone on just before and what will go on immediately afterward. A full characterization of an utterance as a physical event requires the recognition of a potentially unlimited number of distinct points in time, but it is clear that our understanding of an utterance as a *linguistic* event is hindered, rather than helped, by the recognition of this continuous character of speech. Speech normally is represented as a sequence of a small number of discrete segments, strung out in consecutive fashion like beads on a string; although such a *segmental* representation is fairly abstract, it vastly facilitates the discovery of regularity and coherence in language.

It is clear that the role of particular sound differences varies considerably from one language to another. Thus, in English, the vowel sound in the word *bad* is much longer than that in *bat* (more than half again as long), but such a difference in length is always predictable as a function of the following sound, and never serves by itself to distinguish one word from another. In Tahitian, in contrast, essentially the same difference in length is the only property distinguishing, for example, *paato* 'to pick, pluck' from *pato* 'to break out.' A theory of sound that attends only to physical properties has no way of clarifying the quite different functions these properties may have across various languages.

Saussure and the 'Phonemic Principle'

The great Swiss linguist Saussure (1916) was the first to stress that in order to understand the role of sound in language, it is necessary to focus not (just) on the positive properties of sounds, but on their differences. He suggested that in the study of individual languages, as opposed to general phonetics, utterances should be characterized in such a way that two such representations might differ only in ways that could potentially correspond to a difference between two distinct messages in the language in question. Thus, since long and short vowels never (by themselves) distinguish two distinct utterances in English, the difference should not be indicated in that language, while for Tahitian, it must be. A representation with this property will be called *phonological*; it will obviously be specific to a particular language, and the distinctive elements that appear in it can be called the *phonemes* of that language.

While Saussure enunciated this principle quite forcefully and persuasively, he provided few specific details of just what a phonological representation should look like. There are in fact a variety of ways in which his insight could potentially be realized, and much subsequent discussion in phonology hinges on these differences of interpretation.

The Development of Phonology as a Theory

Various individual investigators arrived at conclusions similar to Saussure's about the importance of attention to language-particular sound contrasts. One of these was the Polish linguist Baudouin de Courtenay (1972), whose work actually antedated Saussure's but attracted less attention. He developed a sophisticated view of the relation between phonetics and phonology both in individual grammars and in linguistic change. As transmitted by his later students, Baudouin's views on the nature of the phoneme constituted an important strand in thinking about language as this developed in Russian linguistics in the early years of the twentieth century. This, in turn, provided the background from which the work associated with the Linguistic Circle of Prague grew in the 1920s and 1930s.

Two of the most prominent members of the Prague Circle were Trubetzkoy (1939) and Jakobson (1941). In their studies of Slavic languages and their histories, they stressed the notion that the collection of potentially contrastive sound types in a language was not simply an inventory, but a highly structured system. This system is organized in terms of a small number of mutually orthogonal dimensions (such as voicing, stop vs continuant, nasality, etc.), each of which serves in parallel fashion as the basis of multiple contrasts. The notion that the fundamental terms of sound structure in language are these properties themselves and not (or at least not only) the complete sounds they characterize has remained an important component of most subsequent theorizing.

American Structuralist Phonology

Early thinking about sound structure in America was dominated by the anthropological interests of Franz Boas and focused on an accurate rendering of the sound contrasts in the comparatively 'exotic' indigenous languages of the new world. Boas's student Edward Sapir, however, was concerned to place the study of language in the broader context of an understanding of the human mind and society. Therefore, he stressed (Sapir, 1925) the notion that the elements of sound contrast in a language should be regarded as having a primarily mental reality, part of the speaker/hearer's cognitive organization rather than as external, physical events.

The rise of positivist views of science in the 1930s, and especially of behaviorist psychology, made Sapir's type of mentalism quite marginal, and replaced it with more rigorous operational procedures for investigating notions of contrast. Especially associated with the ideas of Bloomfield (1933) and later structuralists such as Harris (1951), the result was a theory of the phoneme based exclusively (at least in principle) on a set of mechanical manipulations of corpora of observed linguistic data, from which a set of contrasting minimal elements was to be derived. The central notion of this theory was a phonemic representation related to surface phonetic form in a way that would later be formulated explicitly as a condition of *bi-uniqueness*: the requirement that given either a phonetic or a phonemic representation of an utterance in a given language, that could be converted uniquely into the other (disregarding free variation) without additional information.

Generative Phonology

The phonemic theories of American structuralists provided a way to characterize linguistic contrasts, the inventories of sound types used in a given language, and the ways in which sounds can be combined into larger structures, but other aspects of sound structure were less satisfactorily accommodated within those views. In particular, questions of the ways in which unitary meaningful elements change in shape according to their sound context (or 'allomorphy') failed to receive systematic treatment. Since any difference among sounds that could serve to contrast linguistic elements was *ipso facto* a difference between irreducibly basic terms, there was really no way to express the notion that a single item could take a variety of forms (as in the prefixes in *inefficient*, *imprecise*, *irregular*, *illegal*, etc.) except by simply listing the variants. Such a list is undoubtedly appropriate for cases such as the forms of English to be (*am*, *are*, *is*, *was*, *were*, etc.) which are unrelated to one another in form; but in many other cases, the variation is transparently systematic and a function of the sounds in the element's environment. This sort of variation was recognized by structuralist phonologists, but relegated to marginal status.

Beginning with the work of Morris Halle, a student of Jakobson, linguists began to question the centrality of surface contrasts in sound structure. The result was a new view that allowed morphophonemic regularities as well as more superficial ones to be accommodated within a phonological description. The success of this more abstract notion of sound structure in dealing with hitherto irresolvable problems in the description of stress (*see* Suprasegmentals) contributed greatly to its success, and the resulting theory of generative phonology as developed in the work of Halle together with Noam Chomsky rapidly became the dominant view in the field by the middle of the 1960s.

Phonology as a System of Rules and Representations

A basic insight in the development of generative phonology was the proposal that it is not only the representation of linguistic elements in terms of basic contrasts that matters: an adequate theory must characterize what a speaker knows about

the sound system of the language, and that includes regularities of variation and alternation as well as inventories of basic elements. Combining these two aspects of phonological knowledge required the explicit recognition of a system of rules (expressions of regular patterns of contrast and variation in sound shape) in addition to the theory of representations. Developing an adequate theory of phonological rules, in turn, necessitated a notion of phonological representation that was related to surface phonetic reality in a much more complex and indirect way than the phonemic representations of structuralist linguistics. The central problems of phonological theory came to be articulated in terms of the theory of rules, their nature, and their interaction, and the underlying phonological representations that need to be posited in order to allow them to be expressed in their full generality.

Issues in Phonological Theory

As reviewed in the section 'Some History' above, the problem of phonological description was originally conceived as a matter of discerning the range of contrastive sound units in a language and arranging them in a system that brings out the dimensions of their contrast. When phonology is seen as a form of knowledge, however, as generative phonologists have stressed, the sound structure of natural language takes on quite a different form and presents quite different problems. Among these are (1) the nature of underlying ('phonological' or 'phonemic') representations as well as surface ('phonetic') representations; (2) the ways in which phonological regularities serve to relate phonological to phonetic representation, including the interactions that may obtain among regularities; and (3) the relation between phonological form and other aspects of linguistic knowledge, such as word structure (*see* Morphology in Linguistics) and sentence structure. Various aspects of these questions are addressed below.

The Abstractness of Phonological Representation

Initial reaction to the proposals associated with generative phonology centered on its abandonment of a phonemic representation based on the condition of biuniqueness. Relaxing this defining characteristic of structuralist phonemics led to phonological representations that were considerably more abstract in their relation to phonetically observable properties. The proposals of Chomsky and Halle (1968) concerning the analysis of English, for example, involved positing final 'silent *e*' in words like *burlesque* (phonologically /bVrleske/), geminate consonants in words like *confetti* (/kVnfetti/), a distinction among /k, s, c/ such that *acquiesce* is phonologically /æckwiesce/, etc. Indeed, there were no constraints whatsoever on the relation between phonological and phonetic form, apart from the desire to set up underlying forms from which as much variation as possible in the shapes of particular morphological units could be predicted. Since much of this variation is the residue of earlier sound changes that have affected the same element in different ways in different environments, many early generative analyses resembled historical accounts of the language more than they did the knowledge of current speakers.

The perception of such apparently excessive abstractness led to proposals for constraining the operation of phonological rules in grammars, and the kinds of representation that should be posited. Kiparsky (1973), in particular, suggested a variety of conditions that would have the effect of prohibiting rules of 'absolute neutralization' (by which some posited phonological distinction is eliminated uniformly in surface forms, such that it never corresponds directly to a phonetic distinction) and other perceived abuses of the theory's representational freedom. Other researchers, however, have pointed out cases where absolute neutralization does seem to be called for in the analysis of particular languages, since it allows for an explanation of the different behaviors of sets of surface-identical segments within the phonological system. The notion of *learnability* entered into this debate, with proponents of constraints on abstractness arguing that a highly abstract system is not learnable; others have argued that abstract systems are indeed learnable when there is evidence for the abstract structures in the form of alternations. The tension between a constrained universal theory versus an empirically adequate and/or elegant analysis of specific languages is apparent here as in other theoretical debates in the field. At present there is no real consensus in the field as to what, if any, constraints on abstractness should be hypothesized to exist in grammars.

The Interaction of Phonological Regularities

In the nature of a structuralist phonemic representation, all of the regularities expressed in the grammar are mutually independent. That is, it is only necessary to know the phonemic environment of a phoneme to predict its phonetic realization, and it is only necessary to know the phonetic environment of a phonetic segment to establish its phonemic correlate. When the bi-unique relation between these levels of representation is relaxed, however, more complex possibilities arise for regularities to interact with one another.

Consider the formation of English regular plurals, for example. For the words *cat*, *dog*, *horse* (roughly (kæt), (dog), (hors) respectively, phonetically), the corresponding plurals are *cats*, *dogs*, *horses* ((kæts), (dogz), (horsɪz)). Assume that the phonological representations of the nouns are essentially the same as their phonetic forms, and that the regular plural ending has a single constant phonological form: /z/ for concreteness' sake, though the point to be made is independent of this choice. Now there are two distinct regularities that are involved in determining the pronunciation of the plural ending:

a. If the noun ends in a sibilant ((s, z, ʃ, ʒ, t͡ʃ, d͡ʒ)), a vowel (ɪ) appears between the stem and the ending.
b. If the stem-final sound is voiceless, the ending is voiceless ((s)) as well.

Now consider how these principles interact in determining that the pronunciation of *horses* (phonologically /hors + z/) should be (horsɪz). In this case, the conditions for both of the rules above, *b* as well as *a*, are met, and we might expect both to apply, yielding (incorrect) (horsɪs). The relevant observation is the following: the vowel inserted as a result of rule *a* has the effect that the stem and the ending are no longer adjacent, and so rule *b* is inapplicable. That is, the regularity

represented by rule *b* in this case presupposes that the set of clusters of consonants that will remain adjacent in surface forms (a matter that is potentially affected by applications of rule *a*) has been determined. This logical relation of presupposition between rules is generally expressed by saying that rule *a* applies 'before' rule *b*. In some cases, such rule ordering produces *opacity*, wherein the inspection of a surface form seems to show that a rule should have applied but didn't (*underapplication*) or a rule applied that should not have (*overapplication*). In the theory of rule ordering, these effects are explained by rule *b* creating the surface environment in which rule *a* would have applied if *b* had applied first (in the case of underapplication), or rule *b* eliminating the surface environment in which *a* applies, but after *a* has already applied (in the case of overapplication). Crucial to modeling such effects is the notion that the output of rule *a* is an intermediate form in the derivation, and it is to this intermediate form that rule *b* will then apply.

Much of the abstractness of early generative phonological analyses was made possible precisely by the availability of rule ordering as a descriptive device: the possibility of specifying rule interactions such as the above as an independent parameter within grammars. Although arguments for the necessity of such ordering formed an important part of the literature, and particular accounts sometimes involved apparently crucial depths of ordering as great as 12–15, some linguists felt that (as part of the general campaign to reduce abstractness in phonology) stipulated ordering relations ought not to be permitted as a descriptive device. Despite the existence of cases apparently requiring irreducible specification of relative order (e.g., dialects with the same sets of rules and underlying forms, differing in their surface forms only as a consequence of different interactions of the rules) and the fact that all proposed formulations of principles from which observed rule interactions could supposedly be predicted had obvious and well-established counterexamples, a number of linguists have persisted in their belief that 'extrinsic' rule ordering statements ought to be prohibited. This view leaves a number of kinds of empirically observed interactions unaccounted for, a problem that persists as many phonologists have turned from rules to constraints as descriptive devices.

The Structure of Representations in Phonology

As already noted, the description of speech at either the phonetic or the phonological level as composed of a sequence of discrete segment-sized units is an abstraction from physical reality. Its justification comes not from directly observable acoustic properties of sounds, but from the extent to which it allows the analyst to uncover what is orderly and coherent in linguistic structure. By the mid-1970s, however, it had become apparent that a purely segmental organization of representations impeded the description of linguistic regularity in several respects.

One of the first of these problems to be discussed arose from the analysis of systems of tonal contrasts, common in the languages of Africa and Asia and, in fact, much of the world. Careful analysis revealed multiple ways in which tonal properties were problematic for strictly segmental models: first, what appeared to be a single tonal specification might take as its scope more than a single segment (perhaps the vowels of several consecutive syllables, or an entire word); second, what appeared to be a single segment (a unitary short vowel, for example) might have a tonal specification involving two or even more consecutive tonal levels; and third, there was evidence for tones existing in the phonological representation of a word but not belonging to or being directly phonetically realized on any segment in that word. If it is assumed that each of the consecutive segmental units of which a representation is composed bears exactly one specification for each potentially distinctive property, and the specifications of distinct segments are independent of one another, all of these situations are anomalous.

As a result of these observations, the segmental view came to be replaced with an *autosegmental* notion of representation. On this view, specifications for each potentially distinctive property (or feature) succeed one another discretely, but an additional dimension of representation is the specification of the way these are synchronized or aligned with other properties or features. In the limiting case, where each specification for a given feature is temporally aligned with one and only one specification for each of the other features, the standard segmental picture arises; in other cases, the relations among these features are not one-to-one. Once this view was articulated, it became apparent that many properties other than those of tone were also most appropriately described in this way. Nasality, in particular, behaves similarly in many languages, and the very common phenomenon of assimilation (including vowel harmony, voicing assimilation, and assimilation in place of articulation) is often best treated as an alteration in the scope of some features rather than a change in their values.

A theory of autosegmental representations where each feature stands alone would fail to account for the fact that in many cases, groups of features act as a unit. For example, in the domain of vowel harmony, often two or more features harmonize simultaneously (e.g., the features representing backness and roundness). This observation gave rise to the notion that phonological features are not just an unordered set, but instead are organized into a hierarchical arrangement such that, for example, features of consonantal place of articulation can be manipulated by the grammar as a unit. As of the early 1990s there was some degree of consensus on specific groups of features that should be organized under distinct representational nodes in such a *feature geometry*, but with the advent of constraint-based theories, many phonologists turned to other questions and abandoned the effort to work out the full details of a universal feature geometry. At present, many questions in this area remain unresolved.

Another representational issue concerns the existence of structural units larger than the single segment, such as the syllable. Classical generative phonology, as represented by, for instance, Chomsky and Halle (1968), makes no appeal to syllables (or any other unit above the segment). This was not simply an omission, but rather a systematic claim to the effect that segmental specification could always suffice to express any phonological generalization: that is, that any observation involving syllables (of which there are many in Chomsky and Halle, 1968) could be satisfactorily reformulated in a way that dispensed with any units other than segments. The

boldness of this claim invited immediate attack, and it soon became clear that there were indeed aspects of phonological structure that required reference to syllables and other suprasegmental units. The resulting theory of the *prosodic hierarchy*, by which segments are grouped into syllables, themselves grouped together into *metrical feet*, which in turn form constituents of *phonological words* (perhaps with some additional categories, according to some writers), has become another standard assumption about phonological structure.

Interactions between Phonology and Other Areas of Grammar

The original conception of a generative phonology was as a component of the grammar that served to map lexically specified syntactic structures onto phonetic form, a representation appropriate to serve as the instructions to the language-independent mechanisms of speech production. This picture logically entails the notion that words, phrases, and sentences are already fully assembled in the input to the phonology. This assumption, however, has proven to be problematic.

The notion that phonological properties interact with the syntactic environment in which forms occur is quite a familiar one, especially in the description of accent and intonation (*see* Suprasegmentals). Word formation, too, may depend in some instances on phonological properties of roots and affixes (*see* Morphology in Linguistics) in a way that contradicts the assumption that phonology applies strictly to the output of this part of the grammar.

The most extensively elaborated picture of how phonology interacts with the rest of grammar is presented by the theory of lexical phonology (see papers in Hargus and Kaisse, 1993 for introduction and explication). Briefly, this picture distinguishes between lexical and postlexical regularities, with the former applying in a way that interacts with word formation, and the latter applying to a representation in which fully formed words appear in their syntactic context. The lexical rules, in turn, may (depending on the language) be divided into two or more *strata*, for example, rules applying to *roots*, *stems*, or *words*. A process of word formation takes some lexical unit as its input and yields an output (affixed or otherwise altered in form), with this output then subject to appropriate phonological modification. The resultant representation may serve as the input to further *cycles* of word formation plus phonology, until a complete surface word is arrived at. Words, assembled into larger syntactic constructions, are then subject to the post-lexical rules.

While various forms of lexical phonology generally constitute the background assumption of much phonological discussion, such a view of the overall architecture of grammar has at times been rejected. In particular, constraint-based theories involving a single stage in the conversion of underlying to surface form are, in their strictest form, incompatible with the sequential, derivational character of lexical phonological description. Later work in constraint-based models recognized the need for phonology to be sensitive to the internal structure of words and has attempted to reincorporate this sensitivity into the theory in various ways.

Rules versus Constraints in Phonological Description

Formulations of phonological regularities since the 1950s have drawn on the mechanisms of automata theory: typically, these have been expressed as rewriting rules that map an input representation onto an output, one step at a time. In the early 1990s, however, an alternative possibility was suggested. Instead of converting inputs to outputs in several stages, with each step involving the imposition of a single regularity in the computation of a new representation, one might formulate all of the regularities as elements of a single system of constraints. If these constraints are ranked with respect to one another, it is possible to say that any particular constraint may be violated in the output, provided that such a violation is motivated by the need to avoid violating a more important (higher ranking) constraint. The resulting theory provides an architecture of grammar that is very different from that which previously dominated most of the literature in phonology. For example, the kinds of interaction among regularities treated above as matters of rule ordering can no longer be described in this way, since all of the constraints in the grammar apply (in principle) in a single, simultaneous block. Constraints can have a language-particular ranking among themselves, but this is a matter of priority, not serial ordering. Other differences have been alluded to in the discussion above.

Constraint-based theories along the lines of optimality theory (OT; Prince and Smolensky, 1993) became the most popular mode of phonological theorizing in the US in the 1990s. The earliest versions of OT were argued to be very simple, with a set of universal constraints and a parallel input–output mapping. Attempts to fit known phonological patterns into this theoretical framework posed serious problems, however. It was soon acknowledged that not all constraints can be universal; the theory needs to allow for language-specific constraints to be learned. Cases of opacity were also especially problematic, since a strictly parallel model has no way of incorporating the notion of intermediate forms that were crucial to modeling opacity in rule-based phonology. Various attempts were made to work around this problem with a series of add-ons to the original OT proposal, each of which was criticized as excessively powerful, inadequate to account for all types of opacity, and/or a rejection of the notion of parallelism that had made OT appealing to many phonologists in the first place. No consensus has been reached as to the proper treatment of opacity in constraint-based models. Another significant problem was in the failure of constraint-based theories to take the results of research in lexical phonology into account, since the original OT model was, by design, insensitive to word-internal morphological structure. Later models did incorporate word structure in various ways; for example, stratal OT is essentially OT combined with lexical phonology such that input–output mappings are still done in parallel within each level, but different levels (root, stem, word) constitute separate stages in a derivation. The state of constraint-based theories in the early 2010s appears somewhat fragmented, with some theorists pursuing models that look much more like rule-based theory in incorporating serially ordered steps in a derivation, and others positing numerically weighted constraints as opposed to strict rankings. A number of researchers reject constraint-based theories entirely, arguing against them in favor of rule-based phonology on empirical and conceptual grounds; Vaux and Nevins (2008) give an overview of this debate.

Abstract

For over a century and a half, photography has been the most popular and widespread means of making images. The first and primary tool of photography is the camera, and changes in the medium and its applications are often attributed to technical developments in making, reproducing, and distributing photographs. Equally if not more significant, however, have been changes in the ways people think about photography, including ideas about what and how photographs represent, and the roles they have played in social, political, and economic life. This article examines developments and conflicts in the idea of photography within a historical framework of changing cultural practice.

Photography's Origins

The invention of perspective in the fifteenth century laid the foundation for the system of visual representation that became photographic. The camera obscura, used by scientists, artists, and magicians since the Renaissance, is the most important precursor to the camera. By the eighteenth century this device had evolved from a large clumsy apparatus for projecting an image onto a plane surface, to a more portable instrument, used for the curiosity and pleasure of looking at images of all sorts of objects and scenes projected by the lens.

A knowledge of light-sensitive materials was popularly available in Europe by the 1720s, and one of the riddles of photography is why nearly a hundred years passed before this knowledge was applied to fixing the camera obscura's image. Despite a broad fascination with display forms, such as the diorama, that created illusions of realistic representations of nature, the idea of the photograph as a permanent copy apparently did not exist. Suddenly, in the 1820s a range of experimenters began simultaneously to compete to be the first to successfully fix the photographic image; the desire to photograph had emerged.

Photography's invention is generally dated to 1839, when breakthroughs were announced nearly simultaneously in France and England. Louis Jacques Mandé Daguerre's induplicable monochrome on a silver-coated copper plate, and William Henry Fox Talbot's reversed image – the negative – were the first successfully publicized and patented processes. The daguerreotype enjoyed an immediate popularity, setting off a craze which by the end of the year the French press had named '*daguerréotypomanie*.' Talbot's calotype system, on the other hand, based on a negative image that could be used to print a potentially infinite number of positives in as many different sizes, laid the foundation for all subsequent developments in photography. The refinement and diffusion of these two systems, alongside many competitors, had an immediate impact on European social life and spread quickly to North America and colonial outposts.

Photographs appeared in many display forms, as cartes-de-visites and stereographs, in albums and as lantern slides, and photography surfaced as a theme in popular music, on the stage, and in artifacts ranging from home furnishings to fashion accessories. Photography as an *idea* permeated mid-century European popular culture.

Early Applications of the Medium

At the same time that photographic tools and processes were being simplified, an agenda was being established for how the new medium was to be used. This included the people, places, and events represented in photographs and, equally important, who was taking the pictures and who were the intended viewers.

Photographs of People

Within months of Daguerre's announcement, professional portrait studios had sprung up in Paris, and soon studios were established in other major European cities, in New York, and in Washington. From 1860 onward, portraiture expanded to provincial towns, to less industrialized European countries, and to Australia, China, Japan, Mexico, and South America.

The photographic portrait represented a democratization of the painted portrait, and was commissioned first for private use within a family. The rising status of certain photographers led to commissions from men in public life whose positions required an official portrait. Most portraits of individuals followed the strict visual conventions of the painted portrait, a head-and-shoulders composition, with the sitter's head slightly turned to avoid a direct gaze into the camera. Portraits of family groups were common, and a custom quickly developed of photographically commemorating important events such as weddings and graduations. Photographs of deceased relatives, lying peacefully in their caskets, were also highly valued.

In the 1860s, studios began to turn out millions of inexpensive *carte-de-visites*, full- or bust-length portraits of workers, tradespeople, members of the bourgeoisie and aristocracy, native people of the colonies. These mass-produced images were often instrumental in establishing the status of a politician or celebrity, and both the French and British royal families permitted the sales of their images as *cartes*. Through its broad

distribution, the *carte-de-visite* also contributed to forming Western ideals of feminine beauty and fashion, as well as ideas about people from the nonindustrialized parts of the world as exotic and other. The *carte* craze further generated a surrounding industry of albums and holders for cataloguing and exhibiting the growing image collections.

In 1888 George Eastman launched the first Kodak camera, with the slogan 'You push the button, we do the rest,' and immediately opened the practice of photography to a much broader segment of the population. Studio portraiture declined as amateurs began to photograph family and friends. The repertoire of photographic events was also expanded as picture-taking became associated with holidays, family celebrations, and vacation trips. Photographic practice had entered the domestic domain, forming a bridge between personal memory and public history. A hundred years after the first Kodak camera, photography was fully integrated into family social life. In the mid-1980s, for example, over 90 percent of US families owned a still camera and amateurs were taking more than 11 billion photographs a year (Chalfen, 1987). The majority of these pictures were of family members and friends and were rarely seen outside that social group. Nonprofessionals' private photography today accounts for the largest single application of the medium. Studies have shown that people attach enormous value to these images, and losing photographs of family and friends, for example, through fire or war, is often experienced as a greater tragedy than the loss of other material possessions.

Distant Worlds

The early years of photography coincided with the period of colonial expansion and exploration of newly won territory for the industrializing nations of Europe and North America. Wonders of nature, the dynamic new cityscape and its architecture, and the exotic cultures of distant lands held a fascination and attraction for many. The camera was an ideal tool for showing what was new or previously unknown to an audience eager to marvel over sights they could not see with their own eyes. Photography also opened up new territories for tourism by people who, having seen a place in pictures, now had the desire and means to experience it themselves. A new aesthetic of the landscape also stimulated tourism, as for example when photographs of the rocky Scandinavian coasts brought British and German tourists north in the 1870s (Rosenblum, 1984: p. 112).

Photographs of popular European tourist sites, such as the city of Rome and its ruins, were marketed as stereographs. Distant lands of North Africa and the Near East became accessible to the armchair tourists of Europe as early as the 1850s through Francis Frith's photographs. Frith's *Egypt and Palestine Photographed and Described* (1858) was the first of 11 volumes and three sets of stereographs (Rosenblum, 1984: p. 122). His work was motivated in part by a concern over growing French influence in the region, and must be seen in the broader context of British expansionist goals of the period. Local Egyptian photographers also opened studios and marketed their work to the growing European fascination with views of the ruins and landscape of the Near East. Similar patterns developed in India and parts of the Far East. By 1884, for example, several thousand native photographers were in business in China, serving both local clients and the Western trade.

In North America, photography was linked to Western expansion. Photographers accompanied survey teams in order to document areas for future mineral exploitation, rail routes, and civilian settlement, at the same time that they were contributing to the visual discourse of the American frontier and its native peoples. The natural wonders of the wilderness, including Niagara Falls, were immensely popular stereographic themes, used in lantern slide shows and collected in albums. This iconography and the photographers who produced it, such as Carleton Watkins and William Henry Jackson, established the grandeur of the mountain landscape as a symbol of transcendent idealism. Their work also contributed to lobbying efforts to establish a national park system in order to save the pristine wilderness from commercial exploitation by private interests.

Nor did the city escape the camera's gaze. In contrast to images of untouched wilderness and ancient unchanging ways of life, here the focus was on physical transformation. New transport systems, bridges, and buildings made possible by new technologies and materials were transforming the city into a modern metropolis. Urban expansion was a source of national pride, and both governments and private interests supported photographic documentation of the major cities of Europe and North America. Cityscapes in panorama format were especially popular, a parallel to the painted panoramas and dioramas that had emerged as mid-nineteenth century forms of entertainment.

Photography's prominent and various positions in the emergent discourse of modernity was never more evident than in the world expositions, the late-nineteenth century spectacles of science and marketing, combining knowledge and entertainment. Beginning with the Crystal Palace in London in 1851 and followed every few years in Britain, France, and the United States, these major events both symbolized and displayed industrial expansion, made possible by new technologies and materials. Displayed side by side with the symbols of modernity were the exotic products and peoples of the underdeveloped nations, the colonies. At this point in the medium's development, photography provided an unproblematized means of expanding knowledge of the visible world, and served 'the general urge in all industrialized societies to measure, describe, and picture the physical substances of all things on earth and in the heavens' (Rosenblum, 1984: p. 140).

Concepts of the Image

Photography's popularity as a democratic form of self-documentation, intertwined with colonial interests and industrial expansion, point to the camera as a tool that linked seeing and knowledge in new ways. Within the sciences, in the arts, and in social reform movements, distinct and often conflicting visual discourses have developed around the photograph as a source of insight and knowledge. We turn now to the ways of seeing with the camera that were generated within each of these broad fields.

Photography and Science

Within the discourses of science, photography was to be a witness to scientific observation with greater accuracy than the human eye was capable of. In medicine, photography provided close visual description of the human body, and was an aid in documentation and diagnosis of medical problems and also psychological reactions and mental aberrations. Examples are portrait photographer Professor John William Draper's book *Human Physiology* (1856), illustrated with woodcuts based on photographs and Dr. Hugh Welch Diamond, also known for his pictorial art photography, who documented women inmates of the Surrey County Asylum. Charles Darwin's *The Expression of Emotions in Man and Animals* (1872) was illustrated with photographs from a variety of sources. Microscope lenses were developed and the discovery of X-rays by Conrad Wilhelm Roentgen (the 1901 Nobel Prize recipient) led to their immediate use as camera images in medical diagnosis. Motion studies and stop-motion experimentation depended heavily on photographic documentation. Eadward Muybridge's 100 000 images analyzing movements involved in animal locomotion and a range of human activities (including walking, curtseying, and bricklaying) provided a new if contested way of seeing that also influenced the arts, in particular Cubist and Futurist painters.

Taxonomy was a unifying concept of the nineteenth century scientific paradigm, and studies of the human species were formed by the delineation and elaboration of physical and cultural distinctions. Anthropology became a dominant discourse of explanation, based on historical and biological notions of culture, and relying heavily on comparative taxonomic methods in order to systematically catalogue the world's peoples (Edwards, 1997). Photography was central to the anthropometric systems developed to produce comparable data for analysis and classification. The system used by the distinguished British biologist Thomas H. Huxley for the Colonial Office, for example, involved posing individuals naked with a measuring rod in order to produce 'a systematic series of photographs of the various races of men comprehended within the British Empire' (cited in Edwards, 1997: p. 56). These studies of human physiogomy, used to expand evolutionary theory, contained a strong moral dimension, concerned with both creating and sustaining the complex system of social knowledge in which the images operated. Variations on the method were applied in hospitals, prisons, and other institutions where photographs of inmates were used to establish and classify social types.

The 1870s and 1880s also brought about an awareness of the contributions photography could make to anthropological fieldwork, by Edward B. Tylor and others. Yet there are few examples of systematic photographic documentation in ethnographic field studies. Early photography of the ways of life of diverse folk groups was most often carried out by missionaries and educators or by artists working in the pictorial tradition. Edward Curtis, Adam Clark Vroman, Robert Flaherty, and Frances Flaherty documented native American tribal life in its positive aspects, romanticizing in particular the close relationship to nature. Nor was it uncommon for ethnographic photographs from the turn of the century of peasant customs made in a pictorialist style to be used to advance the cause of nationalism, as in several Eastern European countries. The most common reference to an ethnographic photography worth emulating is the classic study of *Balinese Character* (1942) by Margaret Mead and Gregory Bateson, as the 'first saturated photographic research in another culture' (Collier and Collier, 1986: p. 12). Visual anthropology at mid-century was more closely associated with documentary film than with photography. Ethnographic photography survived as an *ideal*, however, despite the general absence of large-scale systematic studies. The British 'Mass-Observation' project in the mill towns of northern England in the 1930s, for example, was designed as an 'objective documentation' of working class life, in the manner of an anthropological study.

The archive has worked hand in hand with the scientific endeavors of accumulating and systematizing evidence. Seen as a repository of visual knowledge, the archive is related to the ideal of a comprehensive collection of images that together represent the whole (other examples being the family album or collection of *carte-de-visites*). The structure of the archive and its classification system was intended to mirror the physical and social world that the collection represented. Following Michel Foucault's groundbreaking archeology of the human sciences (1970), museums of natural and cultural history, as well as police, medical, and other archives, can no longer be seen as disinterested institutions that sustain and perpetuate value-free systems of knowledge, but reflect instead the structures of political and economic interests that gave rise to them. The photograph's evidentiary authority is thus inseparable from the archive as a repository of knowledge and power.

Photography and Art

Contrary to the idea of the photograph as an objective visual record, it has been argued that photography is inseparable from the Western pictorial tradition. Particularly in its relationship to landscape and nature, photography employed a set of conventions and aesthetic standards theorized by the European concept of the 'picturesque.' Emulating themes from the fine arts, many early photographers developed techniques that undermined the sharp literalness of the lens in their aspirations to make images that were at once truthful, beautiful, and inspirational. Exhibiting esthetic photographs in an appropriate context was a paramount goal of the turn-of-the-century Secessionist movements in Europe and the United States, and was important to establishing photography's status as art. Pictorialism in photography was a synthesis of the realism of the camera image, with frequently formulaic romantic compositions of peasant or working class life.

A complex and uneasy relationship between photography and the fine arts has continued, even as the repertoire of art photography has expanded. This is generally beyond the scope of this article, apart from several developments relevant to photography's relationship to the social sciences. On the one hand, themes drawn from peasant and working class life as well as of non-Western people integrated scientific inquiry with romantic images of an exotic or primitive Other as legitimate subjects of photographic art. On the other hand, attempts in the 1920s to define and explore the characteristics which distinguish photography from other visual arts laid the foundation for a more radical 'straight' photography, called New

Realism or *Neue Sachlichkeit* in Europe and North America. The nonmanipulated or spontaneous photograph became a means of exploring and exposing familiar subjects in new ways. These different schools and genres of art photography became more or less systematized as museums began to add photographs to their collections. The Museum of Modern Art in New York is a noteworthy example of a leading museum where a series of influential curators established a vocabulary of photographic practice based on the premises of modernism. By the 1940s, a photographic canon was in place, including a history of art photography with specific artists, works, and genres represented in the museum's collections (Newhall, 1949). Of particular importance to the social sciences was the respect this canon established for the genre of documentary photography as a legitimate form of esthetic practice.

The Photographer as Engaged Observer

Parallel to their idealized representations of European peasants, from the 1850s onward artists began to be concerned with the social and ethical consequences of industrialization, preparing the way for documentary photography's role in social reform campaigns. 'Before' and 'after' images became a staple of reform photography in the 1890s, as evidence of the positive effect the reform school or institution had on its residents. Photographs from the slums of New York (by Jacob Riis) and of child labor conditions (by Lewis Hine) were used to raise the fears and sway the consciences of politicians and a middle-class public. The photography of social reform was closely linked to new means of dissemination: the half-tone process for mass-producing photographs had been developed in the 1890s and a range of new periodicals arose in its wake.

Alongside the popular press' increased use of photographs after the turn of the century, social reform journals were among the first to recognize photography's ability to advocate a cause. Here the American *Charities and the Commons* is noteworthy. The *American Journal of Sociology* was also using photographs to illustrate articles, for example, on housing conditions. This visual material, often by women who held administrative positions in social action agencies, later declined under Albion Small's editorship, as the journal aligned itself with sociology's move to establish itself as a scientific discipline (Stasz, 1979).

By the 1920s, documentary photography, as the genre came to be known, was recognized as an effective means of drawing attention to social issues. The best known example of such an effort was the photographers who worked for the US Farm Security Administration (FSA) under the leadership of Roy E. Stryker in the late 1930s, documenting the effects of the depression on rural Americans and the need for government aid. In other cases, photographers used the documentary form to draw attention to marginalized social groups, occasionally drawing on their own experience as members of the culture they documented. One of the clearest ideological expressions of photographers' identity was the Worker Photography movement, most active in Germany between World Wars I and II. The International Communist Party, convinced that photographs unavoidably reflect the class of the person holding the camera, mobilized workers in a variety of documentary projects and publications. In direct contradiction to a claim of impartiality, this photography based its authority on the photographer's membership in the group. It can thus be seen as a precursor to anthropology's interest in indigenous photographers' images as expressions of their specific cultural perspectives.

The authenticity of the documentary style was based on a complex set of factors. Seldom was the work based on a single photograph, but instead was built up through a series of images witnessing the photographer's proximity to the subject over an extended time. Despite many exceptions, the images also tend to follow a specific visual code. Straightforward photographs of people, taken in their everyday environment under available light conditions, are the most typical. If the subject appears to be aware of the camera, he or she is usually gazing directly into the lens. The photograph's claim to truth is based therefore on the seemingly contradictory appeals of the photographer's simultaneous engagement with and objective distance from the subject.

Photography and Mass Society

Closely related to the ways photography has portrayed its subjects is the effect of images on those who see them, the audience. Photography was a mass medium almost from its inception, as the idea of the photograph and the ways it was marketed had a broad and immediate social and cultural impact. The 'very insatiability of the photographing eye' and the 'omnipresence of photographed images' position the medium in a vortex of complex moral, ethical, political, and esthetic issues. Sontag's influential book of essays *On Photography* (1973) brought many of these issues up for debate. Yet the exact nature of the photograph's appeal and its effect on its viewers has remained elusive. Despite extensive research on photography's impact on attitudes and behavior, results have been either inconclusive or too context-specific (regarding the viewer's age and background or the viewing context) to support any general conclusions. What is evident, instead, is a widespread belief in the photograph's influence which has in turn led to specific applications of the medium based on conceptions of the nature of photographic communication as a highly unstable synthesis of factual information and seductive attraction.

From the 1850s photographs began to be used alongside other illustrations in some magazines, and the widespread application of the half-tone process in the 1890s coincided with the emergence of new audiences in Europe and the United States. Photography was thought to appeal in particular to people who were either nonliterate or had not yet mastered the language of their new country. A new inexpensive illustrated press arose that used photography in often sensational ways, and photographs began to appear in advertising. Political campaigns made extensive use of photography from the 1920s onward, in documentary forms described above, but also in photomontage and posters. The reticence of many newspapers to make extensive use of photography (for example, the morning newspapers 'of record' in New York and London) is an exception which nevertheless rests on the same notion of the photograph's communicative power. The photograph, if seen as an unmediated copy of nature, does not require language or reason to be understood, but appeals instead directly to the emotions. Newspapers and other media that wished to base their appeal

on rationality excluded photographs from their pages. Even if an image were manipulated through technical or other means, the message that the audience saw or 'received' was accepted as representing reality.

The model of mass communication that emerged first in the United States and dominated research for several decades was based on the notion of communication as a successful 'transmission' of a message from an active and powerful source to a passive receiver. The origins of the model and the research it generated can also be traced to growing concern over the power of the media, particularly in the service of political propaganda and the rise of fascism in Europe after World War I. Although only sporadically applied in research on photography, the transmission model of communication served as the underlying framework of explanation of photography's influence on its audience. The power of images is assumed to be greater, for example on the relatively unformed psyches of children and youth. 'Moral panics' continue to pursue the image and its influences, giving rise to research on Hollywood films in the 1930s, on comic books in the 1940s, on television's effects on children in the 1950s and 1960s, and video games at the turn of the century.

Countering the transmission model of photography's influence on its audience is the perspective that considers photography as a cultural practice and phenomenon which participates in the construction of power and meaning through the mutual and intertextual establishment of social and political institutions and forms of visual expression. The cultural perspective views the audience not as passive receivers, but as members of a (sub)culture who employ cultural knowledge as they produce, consume, and interpret photographs. The cultural perspective does not deny the power of the media, but rather sets it in a historical, social, or political context, and examines how the media use photographs to address or position the viewer in specific relationships to media content. The perspective shifts the emphasis from an inquiry into photography's impact on individual or group attitudes and behavior to an examination of the ways photography is used in the construction of meaning, often focusing on social values and the use of stereotypes. The medium has been decisive, for example, in the production of visual representations of gender and gender relations, as revealed in Erving Goffman's study of advertising (1979). Other studies have demonstrated how media images of women not only establish standards of feminine beauty, but also link the image of the female body to products and services in a process of commodification that objectifies all women (cf Williamson, 1978; Irigaray, 1985; Bordo, 1993; Solomon-Godeau, 1991). Other analyses have provided insights into the formation and perpetuation of stereotypes of race, in advertising but also in the news media, with groundbreaking work carried out at the Centre for Contemporary Cultural Studies in Britain in the 1970s.

Issues of media power and influence are also linked to photography through a growing concern over the image's role in surveillance. Cameras, in addition to their continually expanding position in private life, are used increasingly in both public and commercial spaces for the ostensible purpose of increasing security and preventing crime. Yet the images taken by these cameras also raise issues of the photograph's potential for restricting, documenting, and controlling individual behavior. As technology extends the capacity to send images over global networks, the specter is raised of expanding spheres of media influence and control that transcend the nation state. At the same time, the interactive aspects of many contemporary media raise the possibility of individual and group autonomy from transnational media content, and the ability of the individual to form and reform images that are sent and received. The cultural impact of these relatively new image technologies is a current topic of debate, particularly with regard to the moral and ethical implications of their distribution and use.

Technology and Revisions of Photographic Meaning

A central question throughout photography's history is whether the meaning of the photograph is a function of the medium *per se* and its technical, chemical, and optical relationship to the subject in front of the camera, or is formed instead through the culture which surrounds it. Benjamin described how photographic reproduction and mass distribution irrevocably altered the individual's encounter with the original, following a more general argument developed within the Frankfort School over the hegemonic power of cultural production in mass society. Yet it was not until the 1970s that a number of theorists began to address the specific problem of photographic meaning, particularly issues related to what and how the photograph represents. Roland Barthes (1977) used a semiotic analysis to unlock the problem of 'the photographic paradox': that is, the photograph represents an analogic reproduction of reality or a message without a code, and simultaneously a connotation or coded message, representing what society thinks about the subject. The major task of the denotative aspect of the image, according to Barthes, is to naturalize the cultural, that is, to transform cultural values into a message that can be 'read' as self-evident, as nature.

The deconstruction of the camera as a cultural artifact and of photography as deeply informed by culture continued on several parallel fronts. The model of the observer that dominates Western science, defined by the Cartesian perspectivalism and the direct gaze, is encoded in the optical system of the camera. The model thus defines a particular relationship between seeing and knowledge that privileges the authority of this gaze and its representations. This 'way of seeing' was critiqued most forcefully in relation to documentary photography for its dehistoricized view of marginalized social groups, a view that in turn established a visual code for representing the Other (Bolton, 1989). Because photography has been constructed as a predominantly male practice, reinforced by the observer's gaze as male, female also becomes Other. Extensions of this critique to the uses of photography in the social sciences have implicated anthropology in particular for constructing its subjects as visually exotic. Related to this phenomenon, as mentioned above, is the institutional gaze, embodied and perpetuated through the archive, the museum, or the press (Tagg, 1988).

In the 1970s, anthropologists also began to criticize the use of film and photography in fieldwork. Instead of being informed by anthropological concepts, the Western anthropologist's visual records reflected 'his' own culture, coded through the practices of family photography. Within the

subfields of visual anthropology and sociology in the United States and Britain and their influential journals, this insight was variously developed into a broader perspective on photography, film, and media in general as sources for studying the cultural values and perspectives of those who create the images. This in turn supported a shift from image analysis to the study of the social and cultural practices in which photography is embedded. This complemented the critique being directed at the field of anthropology as a whole for perpetuating its colonial heritage through techniques of 'writing culture' that represented its subjects as Other (Ruby, 1982). Anthropology's continuing interest in the photography of indigenous peoples and other subcultural groups reflects on the one hand a recognition of photography as a significant source for cultural analysis and on the other, attempts by the field to integrate the anthropological subject's own understandings into research and reports. Current ethnographic studies of media practices frequently include investigations of how images are interpreted and used by ordinary people. The photographic practices of professionals has been largely neglected, however, apart from the many biographies of well-known photographers and analyses of their work.

Digital techniques of making, reproducing, and transmitting photographs have contributed to undermining the authority of the photograph as analog or direct copy of reality. In the mid-1980s, the digitized image was seen by many, particularly within the press, as a direct challenge to established beliefs about how the photograph represents. Gradually the technique has been integrated into professional and private practices of making and distributing images, stimulating the rise of new media networks. The immediacy of image transfer and the portability of the technology have vastly increased the number of photographs in circulation, including those depicting war and human suffering. Some analysts argue that this phenomenon results in 'compassion fatigue,' reducing the moral impact of the image (Moeller, 1999). In the meantime, new applications of interactive image technologies are emerging in the arts, in youth culture, and in diasporic communities. The digital transfer of images globally has given rise in some quarters to a utopian vision with the photograph as a cornerstone of a global visual culture. More realistic analyses point to the diversities of culture worldwide and the continued vast inequalities in access to these technologies as critical impediments to a hegemonic visual culture.

Editor's Note

Since the original publication of this entry, digital photography has replaced traditional film images almost completely and photographic software for the manipulation of digital images (e.g., Photoshop) has become a cultural commonplace. A fine and current study of digital photography is Lister M., 2013. On the larger aesthetic of the photographic medium in the digital age, see Pirenne and Streitberger, 2013. The original entry provides an in-depth discussion of the uses of photography in anthropological research. A fascinating contemporary application of the medium in that discipline is Filip de Boeck et al., 2014.

Physical Activity and Health

Abstract

This article summarizes findings on the relationship between physical activity and various aspects of physical and mental health. Persons who engage in regular physical activity have a lower overall mortality rate as well as a reduced risk of developing coronary heart disease, stroke, colon cancer, breast cancer, diabetes, arthritis, osteoporosis, and obesity. Depression-reducing effects of physical exercise have been found in correlational as well as clinical studies and can be regarded as well confirmed. Regarding anxiety, acute exercise leads to a reduction in state anxiety that lasts for about 1–1.5 h after the exercise is terminated. Finally, evidence from randomized studies suggests that regular physical activity (chronic exercise) improves symptoms in patients suffering from anxiety disorders.

Introduction

The past decades have witnessed a burgeoning of research examining the impact of physical activity on attaining optimal health and preventing disease. Today, overwhelming evidence supports the benefits of exercise for various aspects of physical health. However, exercise has also been shown to be beneficial for maintaining or improving mental health. Unfortunately, our knowledge of the mental health benefits of exercise is still rather limited in comparison to what we know about its physical health benefits. This article provides an overview of the major findings regarding the physical and mental health effects of physical activity.

The Effects of Physical Activity on Physical Health

Overall Mortality

Epidemiological studies suggest that persons who engage in the recommended amounts of physical activity (150 min per week in moderate-intensity activity, 75 min per week in vigorous-intensity activity, or a combination of the two intensities) have overall mortality rates (mortality from all causes) that are 20–30% lower than those of persons who do not reach these amounts (PAGAC, 2008). This finding is supported by longitudinal research examining how changes in the level of cardiorespiratory fitness may affect subsequent mortality risks. For example, in a study by Blair et al. (1995), healthy men with an initially low level of cardiorespiratory fitness participated in two exercise tests about 5 years apart. 5 years after the second exercise test, men in the bottom fifth of the initial fitness distribution who improved their fitness to at least a moderate level had a 44% lower mortality rate than men who remained in the bottom fifth. Similar results had already been found by Paffenbarger et al. (1993) in a cohort of initially sedentary Harvard alumni. The men in this study who started and maintained moderately intense activities extended their longevity by 0.72 years on average.

Cardiovascular Diseases

Cardiovascular diseases (CVDs), in particular coronary heart disease (CHD) and stroke, are major causes of death, disability, and health care expenditures in Western societies. There is clear and strong evidence that, within populations, the incidence of CVD (including CHD, stroke, hypertension, rheumatic fever, congenital heart defects, congestive heart failure, and peripheral vascular disease) is inversely related to habitual physical activity levels (Bauman and Owen, 1999; Janssen, 2012; PAGAC, 2008). Some of the studies in this field demonstrated a dose–response gradient between level of physical activity and risk of CVD outcome. Dose–response relationships were also found in investigations in which measures of cardiovascular fitness, instead of physical activity estimates, were related to CVD mortality.

Coronary Heart Disease

One of the first studies to systematically analyze the association between physical activity and risk of CHD was conducted by Morris et al. (1953), who examined 31 000 employees of the London Transport Executive. A comparison between bus drivers and bus conductors revealed that physically active conductors clearly had a lower risk of a 'first coronary episode' than sedentary drivers. Classifying physically active and inactive people according to job title or occupational activity is typical for studies published before 1978. In the following years, level of physical activity was defined mostly by self-report measures of leisure-time activity or by indices that combined levels of occupational and leisure-time activities. More recent investigations have also emphasized the necessity to control for potentially confounding variables (e.g., age, sex, functional status) and to adjust for factors that are considered causal links between physical activity and CHD, such as serum cholesterol, blood pressure, diabetes, or body mass index.

A vast body of scientific literature indicates that physical activity is causally linked to a reduced risk of CHD. A review conducted on 30 studies published since 1996 suggests that the risk of developing CHD is 19% lower in moderately active (3–6 METs (metabolic equivalents)) men and even 39% lower in vigorously active (>6 METs) men than in men with a low (<3 METs) activity level (PAGAC, 2008). Furthermore, there is strong evidence that this relationship holds true for both men and women. For example, findings from a prospective study among 72 488 female nurses who were 40–65 years old at the beginning of the study suggest that sedentary women who became active in middle adulthood or later had a lower risk of

coronary diseases than their counterparts who remained sedentary. Relative to women who walked infrequently, those who walked at a brisk pace three or more hours per week had a multivariate relative risk (RR) of 0.65 for coronary events (Manson et al., 1999). Physical exertion may temporarily increase the likelihood of an acute coronary event among persons with advanced coronary atherosclerosis who are not used to regular exercise. Although this risk needs to be taken seriously, it does not affect the general fact that physical activity is associated with a substantially lower overall risk for CHD.

Stroke

Today, we know that low physical activity and low cardiorespiratory fitness are also linked to an increased risk of cerebrovascular disease (stroke). Evidence suggests that the protective effects of physical activity and fitness emerge for both ischemic and hemorrhagic strokes. A literature review of 19 studies published since 1996 suggests that the risk of suffering a stroke is roughly 30% lower in moderately (3–6 METs) and vigorously (>6 METs) active men and around 25% lower in moderately and vigorously active women than in their low (<3 METs) active counterparts (PAGAC, 2008).

Biological Mechanisms

Several biological mechanisms may be responsible for the beneficial effects of physical activity on cardiovascular risks. These mechanisms involve the impact on blood pressure, atherosclerosis, plasma lipid/lipoprotein profile, availability of oxygenated blood for heart muscle needs (ischemia), thrombosis, heart rhythm disturbances, overweight, and healthier distribution of body fat.

Cancer

Cancer is one of the leading causes of death in industrialized countries. It is predicted that this proportion will increase in the coming years. Numerous studies have examined the role of physical activity in the prevention of cancer (Sternfeld and Lee, 2009). The relationship between physical activity and reduced cancer risk has been found most consistently for colon and breast cancer (PAGAC, 2008). There is some evidence supporting an association between physical activity and risk for lung cancer (Tardon et al., 2005) and prostate cancer (Lee, 2012).

Colon Cancer

Systematic literature analyses reveal that colon cancer is probably the most often-studied cancer in the field of physical exercise epidemiology. More than 50 studies (cohort and case–control studies) on colon cancer have been published. In sum, these studies indicate that physically active (or fit) persons have a markedly lower risk of developing colon cancer than inactive persons. A meta-analysis by Wolin et al. (2009) reported a risk reduction for colon cancer of 24% for physically active individuals (RR = 0.76 with a 95% confidence interval of 0.72–0.81). Analyses with at least three levels of physical activity suggest the existence of a dose–response relationship: Individuals with the highest level of activity had the lowest risk of colon cancer, those with the lowest level of activity had the highest risk, and those in between showed a risk that was also in between. Such dose–response relationships are a strong argument in support of the hypothesis that physical activity and colon cancer are causally linked. As a biological explanation for the association between physical activity and colon cancer, it has been proposed that physical activity reduces gastrointestinal transit time and thus diminishes the contact duration between the colon mucosa and potential carcinogens in the fecal stream.

Breast Cancer

A literature review by Friedenreich and Cust (2008) included the results of 87 studies on physical activity and the incidence of breast cancer. Overall, the data are fairly consistent with the view that physical activity and the risk of developing breast cancer are inversely connected. The authors reported that the average risk of breast cancer was 25–30% lower in the most physically active group than in the inactive group. A meta-analysis by Monninkhof et al. (2007) yielded a smaller risk reduction for physically active women: Here, the RR was calculated with RR = 0.81 (95% confidence interval: 0.73–0.89), meaning that physically active women had a 19% reduction in the risk of developing breast cancer compared to their inactive counterparts. Dose–response analyses suggest that females need to exercise on a level that is at least equivalent to brisk walking for a minimum of 45–60 min day^{-1} on 5 or 6 days per week (McTiernan, 2008).

Physical Activity among Cancer Patients

The results reported in this overview focus on physical activity (or fitness) in the primary prevention of cancer. In recent years, several studies have been conducted, which look at the effects of physical activity in the treatment and rehabilitation of cancer patients (Sternfeld and Lee, 2009). There is some evidence that being physically active after being diagnosed with cancer may be beneficial to cancer treatment and the patients' quality of life (Speck et al., 2010).

Further Chronic Diseases

Level of physical activity has been related to further chronic diseases and conditions, in particular to diabetes, arthritis, osteoporosis, and obesity. Several prospective cohort studies lend strong support to the hypothesis that regular physical activity offers protection against the risk of non-insulin-dependent diabetes mellitus (Middelbeek and Goodyear, 2012). Reducing obesity through increased physical activity alone is a relatively slow process. Physical activity programs in combination with strategies of dietary management seem to be more effective in this regard (Ross and Janssen, 2012).

The Effects of Physical Activity on Mental Health

Numerous reviews and meta-analyses have summarized the literature dealing with the psychological effects of physical activity (Buckworth et al., 2013). In studies examining the effects of physical activity on mental health, the most frequently observed outcomes include depression, anxiety, mood, self-esteem, perceived stress, and cognitive functioning. In recent years, the focus of research has been extended to include the role

of physical activity in the development and treatment of mental disorders such as schizophrenia, dementia, personality disorders, or eating disorders. Subsequently, we focus on the associations of physical activity with depression and anxiety.

Depression

Results from cross-sectional studies suggest a substantial relationship between physical activity and reduced symptoms of depression in men and women (Buckworth et al., 2013). This relationship holds even when adjusted for potentially confounding factors. A summary of the existing literature led to the conclusion that physically inactive persons are twice as likely to have symptoms of depression than their physically active counterparts. The association between level of physical activity and depression has been found in the general population as well as in clinical subpopulations.

Cross-sectional studies leave the question unanswered whether physical activity has an effect on depression, or whether persons with good mental health are simply more likely to be active. In an attempt to resolve this problem of causality, cohort studies have been conducted in which the relationship between physical activity and depressive symptoms were observed under a longitudinal perspective. One of these cohort studies was conducted by Paffenbarger et al. (1994), which revealed that the level of physical exercise reported at an initial interview was predictive of physician-diagnosed depression approximately 25 years later. In this investigation with 10 201 participants, the RR of depressive symptoms was 27% lower for men who had reported spending more than 3 h engaging in physical activities each week than for men who had reported no such activities. However, in other population studies, the level of physical exercise at baseline was not a risk factor for incidence of depressive symptoms years later (Weyerer, 1992). Thus, the empirical evidence from cohort studies is still limited and inconsistent.

Another approach for resolving the problem of causality is provided by intervention studies conducted in community or laboratory settings. A classic and often-cited work in this field is an experimental study by McCann and Holmes (1984). Altogether, 43 women students who scored higher than the cutoff point on the Beck Depression Inventory were randomly assigned to one of three groups: (1) aerobic exercise group, (2) placebo group, and (3) no treatment group. After 5 weeks, the aerobic exercise group showed a significant reduction in depressive symptoms compared with the other two groups, supporting the hypothesis that increased physical activity results in a reduction in depression. More recently, Blumenthal et al. (2007) compared the efficacy of physical activity to that of pharmacotherapy on the basis of a randomized controlled intervention study. A total of 202 sedentary adults diagnosed with major depression were assigned to 16-week interventions of antidepressant medication (sertraline), placebo pills, home-based aerobic exercise, or supervised exercise. Improvement was defined as no longer meeting the clinical criteria for depression (i.e., remission). At the end of the intervention period, the remission rates were 47% for medication, 45% for supervised exercise, and 40% for home-based exercise, but only 31% for placebo pills, suggesting that the antidepressant effects of regular exercise were comparable to those of pharmacotherapy.

Results on the dosage of physical activity that is needed to elicit an antidepressant effect are provided by Dunn et al. (2005). In this study, 80 adults diagnosed with mild-to-moderate major depressive disorder were randomly assigned to five groups: Four groups participated in 12-week programs of aerobic activity that varied by energy expenditure (low vs high dosage) and frequency (3 vs 5 days a week), and one group (control condition) participated in a 12-week program of flexibility training three times a week. The reduction in depression was significantly greater for the high-energy expenditure condition ($17.5\ \text{kcal} \times \text{kg}^{-1} \times \text{week}^{-1}$) than for the low-energy expenditure condition ($7.0\ \text{kcal} \times \text{kg}^{-1} \times \text{week}^{-1}$) or the control condition (flexibility training), which both showed comparable levels of depression reduction. Whether the exercise was done three or five times per week (frequency factor) did not affect the level of depression. These results suggest that patients with major depressive disorder can be effectively treated with an aerobic exercise program which is based on an energy expenditure of about $17.5\ \text{kcal}\ \text{kg}^{-1}$ of body weight per week (this dosage corresponds to the public health recommendations for physical activity).

Several biological and psychosocial mechanisms have been proposed to explain the antidepressant effects of physical activity. In particular, it has been hypothesized that physical activity may induce changes in brain neuroreceptor concentrations of monoamines (norepinephrine, dopamine, or serotonin) or endogenous opiates (endorphins and enkephalins), which in turn are responsible for changes at the affective level. However, the observed depression-reducing effects of physical exercise may also be mediated by psychological factors such as exercise-induced feelings of mastery and self-efficacy, or by positive social and emotional experiences in the sport context (Buckworth et al., 2013).

Anxiety

Research also suggests that physical activity may be linked to a reduction in anxiety. The psychological assessment of anxiety usually includes state and trait measures. State measures refer to the actual feeling of anxiety, whereas trait measures evaluate the stable personality characteristic of anxiety. In physical activity research, state measures have been used in pre–post designs of intervention studies to explore whether a specific activity episode (acute exercise) has the potential to cause changes in currently experienced anxiety (state anxiety). Results are relatively unequivocal in this respect. Immediately after a session of physical activity, most people report a decrease in state anxiety, which is still detectable 1–1.5 h after the end of the training (Cox et al., 2004; Hale et al., 2002; Knapen et al., 2009). While the short-term effects of acute physical activity on state anxiety are well documented, the long-term effects of chronic (habitual) physical activity on trait anxiety are still subject to debate: A meta-analysis by Herring et al. 2010 confirmed the causal link between regular exercise and trait anxiety, whereas meta-analyses by Long and van Stavel (1995) and Schlicht (1994) did not find convincing evidence in support of this effect.

One of the best randomized studies to examine the therapeutic benefits of regular physical activity in clinically diagnosed anxiety patients is still that conducted by Broocks et al.

(1998). A total of 46 patients with panic disorders with or without agoraphobia were assigned to 10 weeks of (1) a moderate-running program, (2) an anxiolytic pharmacotherapy (clomipramine), or (3) a placebo pill 'treatment.' Compared to the placebo condition, both the running program and pharmacotherapy led to a significant decrease in anxiety symptoms. However, clomipramine improved anxiety symptoms earlier and more effectively than the running program (here it took longer to relieve symptoms). Despite this limitation, the results suggest that regular aerobic exercise alone has the potential to lead to a substantial clinical improvement in patients with panic disorder.

Conclusions

There is strong evidence that physical activity is significantly associated with reduced risk of all-cause mortality, CVD, colon and breast cancer, non-insulin-dependent diabetes, arthritis, osteoporosis, and obesity control. Findings also suggest that regular physical activity may play an important role in the prevention and treatment of mental diseases, including depression and anxiety. Less is known about the psychological and physiological mechanisms behind these antidepressant and anxiolytic effects. The recommended dose for improving physical health is 150 min week^{-1} of moderate-intensity physical activity (3–6 METs) or 75 min week^{-1} of high-intensity physical activity (>6 METs) or any equivalent combination of the two intensities (WHO, 2010). But how much physical activity is needed to improve or maintain psychological well being? The mental health benefits of physical activity are probably not only a matter of expended kilocalories (if at all), but also of activity-related social interactions and emotional experiences. Clarifying the mechanisms by which physical activity may affect mental health dimensions will be a challenge for sport and health psychology in the coming years.

Abstract

Worldwide it has been estimated that physical inactivity alone accounts for the premature loss of ~5.2 million lives per year. Sedentary and inactive people should be given opportunities to become physically active, and those who are minimally active should be supported in doing more. Through community organization physical activity levels can increase among all individuals living in communities and bring about considerable health benefits. Approaches that demonstrate an acceptable level of effectiveness in increasing physical activity across different ages, social groups, and countries exist. For the whole population, there is much to be gained through policies and environmental supports, particularly through partnerships with the sectors of transport and urban planning that can increase opportunities for physical activity within communities.

Foundations for Physical Activity Promotion

Physical inactivity (PIA) is an independent risk factor for a number of noncommunicable diseases (NCDs) worldwide, such as coronary heart disease, type 2 diabetes mellitus, colon cancer, and breast cancer, where it has been estimated that PIA alone is responsible for the premature loss of ~5.2 million lives per year (Lee et al., 2012). Further evidence demonstrates a positive relationship between participation in regular physical activity (PA) and health improvement (Physical Activity Guidelines Advisory Committee (PAGAC, 2008)). Evidence also exists supporting the quality of life enhancing benefits of regular PA as seen among adults and older adults (Brown et al., 2004).

Despite over a decade of efforts to translate this information and promote PA within communities, physical inactivity remains a serious public health challenge (Pate et al., 1995; Department of Health and Human Services, 1996). The most recent prevalence data summarizing global PA patterns indicate that a third of all adults and four fifths of youth/adolescents are physically inactive (Hallal et al., 2012; **Table 1**). The prevalence of physical inactivity is consistent across high, middle, and low income countries (Hallal et al., 2012). What's even more alarming is that more than half of the world's adults are not participating in the minimal amount of PA necessary to obtain some health benefits (Hallal et al., 2012). Men in general are more likely to meet PA guidelines than women. These levels of participation fall far short of the updated PA guidelines in the United States (PAGAC, 2008) and those issued by the World Health Organization (WHO, 2010) and other organizational bodies (European Union Sport and Health Working Group, 2008; **Table 2**). In addition to moderate- and vigorous-intensity aerobic PA many recommendations/guidelines suggest that every adult should perform physical activities that maintain or increase muscular strength and endurance and skeletal health and function for a minimum of 2 days each week (PAGAC, 2008; WHO, 2010). Participation in aerobic PA and muscle strengthening physical activities above this minimal recommendation provides additional health benefits and results in higher levels of physical fitness (PAGAC, 2008).

Understanding why some people are more physically active than others is fundamental to developing strategies and/or specific interventions designed to promote PA among individuals. Bauman et al. (2012), in their most recent review of reviews examining both the correlates (factors associated with PA) and determinants (those factors with a causative relationship to PA), identified age, sex, self-efficacy, and motivation as being associated with PA, with the broader influences on PA behavior of social, cultural, and physical environmental factors playing key causative roles. Therefore current evidence suggests that the successful promotion of a physically active lifestyle involves a multitude of complex variables working together, including personal, programmatic, environmental, and related factors. To achieve long-term changes in health-related behaviors, individual, social, environmental, and medical factors must be addressed collectively with the growing realization that the physical environment is key in promoting or inhibiting PA even among the most motivated of persons (Bauman et al., 2012). A future understanding of how each individual's genetic, evolutionary, and personal characteristics interact with her or his physical and social/cultural environment in being physically inactive or active is critical to effective promotion efforts (Bauman et al., 2012).

Table 2 Physical activity guidelines for adults and youth

Physical Activity Guidelines for Americans:

Children and adolescents should do 60 min (1 h) or more of physical activity daily.

- *Aerobic*: Most of the 60 or more minutes a day should be either moderate- or vigorous-intensity aerobic physical activity, and should include vigorous-intensity physical activity at least 3 days a week.
- *Muscle-strengthening*: As part of their 60 or more minutes of daily physical activity, children and adolescents should include muscle-strengthening physical activity on at least 3 days of the week.
- *Bone-strengthening*: As part of their 60 or more minutes of daily physical activity, children and adolescents should include bone-strengthening physical activity on at least 3 days of the week.

All adults should avoid inactivity. Some physical activity is better than none, and adults who participate in any amount of physical activity gain some health benefits.

- For substantial health benefits, adults should do at least 150 min (2 h and 30 min) a week of moderate-intensity, or 75 min (1 h and 15 min) a week of vigorous-intensity aerobic PA, or an equivalent combination of moderate- and vigorous intensity aerobic activity. Aerobic activity should be performed in episodes of at least 10 min, and preferably, it should be spread throughout the week.
- For additional and more extensive health benefits, adults should increase their aerobic PA to 300 min (5 h) a week of moderate intensity, or 150 min a week of vigorous intensity aerobic PA, or an equivalent combination of moderate- and vigorous-intensity activity. Additional health benefits are gained by engaging in PA beyond this amount.
- Adults should also do muscle-strengthening activities that are moderate or high intensity and involve all major muscle groups on 2 or more days a week, as these activities provide additional health benefits.

Global Recommendations for Physical Activity, World Health Organization:

In order to improve cardiorespiratory and muscular fitness, bone health, and cardiovascular and metabolic health biomarkers:

- Children and youth aged 5–17 should accumulate at least 60 min of moderate- to vigorous-intensity physical activity daily.
- Amounts of physical activity greater than 60 min provide additional health benefits.
- Most of the daily physical activity should be aerobic. Vigorous-intensity activities should be incorporated, including those that strengthen muscle and bone*, at least 3 times per week. For this age group, bone-loading activities can be performed as part of playing games, running, turning, or jumping.
- Adults aged 18–64 should do at least 150 min of moderate-intensity aerobic physical activity throughout the week or do at least 75 min of vigorous-intensity aerobic physical activity throughout the week or an equivalent combination of moderate- and vigorous-intensity activity.
- Aerobic activity should be performed in bouts of at least 10 min duration.
- For additional health benefits, adults should increase their moderate-intensity aerobic physical activity to 300 min per week, or engage in 150 min of vigorous-intensity aerobic physical activity per week, or an equivalent combination of moderate- and vigorous-intensity activity.
- Muscle-strengthening activities should be done involving major muscle groups on 2 or more days a week.

In order to improve cardiorespiratory and muscular fitness, bone and functional health, reduce the risk of NCDs, depression and cognitive decline:

- Older adults should do at least 150 min of moderate-intensity aerobic physical activity throughout the week or do at least 75 min of vigorous-intensity aerobic PA throughout the week or an equivalent combination of moderate- and vigorous-intensity activity.
- Aerobic activity should be performed in bouts of at least 10 min duration.
- For additional health benefits, older adults should increase their moderate-intensity aerobic physical activity to 300 min per week, or engage in 150 min of vigorous-intensity aerobic PA per week, or an equivalent combination of moderate-and vigorous-intensity activity.
- Older adults, with poor mobility, should perform physical activity to enhance balance and prevent falls on 3 or more days per week.
- Muscle-strengthening activities, involving major muscle groups, should be done on 2 or more days a week.

When older adults cannot do the recommended amounts of physical activity due to health conditions, they should be as physically active as their abilities and conditions allow.

Behavioral and Social Strategies for Promoting Physical Activity

Within the scope of health promotion is the necessity to support individuals attempting to make positive health behavior changes. More specifically, sedentary people should be given opportunity to become physically active, and those who are minimally active should be supported in doing more. However, behavior change for PA, along with many other personal habits, can be quite difficult. Therefore, the field of health promotion typically utilizes theories and models when promoting individual or community-based interventions, including increases in PA. A theory refers to a systematic view of a behavior by specifying relationships between variables and predicting specific behaviors and situations (Glanz et al., 2002). A model is defined as a hypothetical depiction of a behavior or situation (Glanz and Rimer, 1995). Models do not attempt to understand the variables underlying a particular behavior, but rather to represent what is happening with a particular behavior. Theories and models are used in PA promotion as they (1) provide a framework for better understanding adoption of the behavior, (2) can help practitioners understand why an individual has stopped PA participation, and (3) allow the practitioner to identify which types of individuals respond to which types of PA promotion strategies.

Intrapersonal and Interpersonal Concepts and Principles in Promoting Physical Activity

Learning theory is a concrete foundation and strategy for facilitating PA related behavior change (Glanz and Rimer, 1995). Learning theory describes how individuals acquire, enhance, or make changes in knowledge, skills, and values (Nutbeam and Harris, 1999), and also reflects the process through which a PA behavior change occurs. Learning theory

is based on antecedents and consequences: an antecedent is a preceding event or circumstance that prompts PA behavior, while a consequence is the result of the antecedent behavior, or the immediate benefit/consequence. Theory-based behavioral interventions are an effective means for increasing PA among sedentary adults (Greaves et al., 2011), and people who receive learning theory-based strategies increase their exercise adherence considerably more than those who initiate exercise programs with no theory-based strategies (Marcus et al., 2006). Theory-based interventions that are tailored to each individual's specific interests, preferences, and readiness for change can teach behavioral skills that help incorporate exercise into lifelong routines (Kahn et al., 2002; PAGAC, 2008).

Transtheoretical Model

The Transtheoretical Model (TTM) has been used to explain health behaviors including smoking cessation, weight control, high-fat diets, adolescent delinquent behaviors, condom use, mammography screening, and sunscreen use (Prochaska et al., 1992). The TTM incorporates both cognitive theories and behavioral strategies to tailor interventions to the individual. Cognitive processes are used to change the way we think about activity, while behavioral processes are used to change/initiate the actual behavior itself. The TTM has also been used to understand PA behavior and to create PA interventions (Marcus and Forsyth, 2009), which have been shown efficacious in increasing PA among sedentary adults (Marcus et al., 1992). The TTM proposes that individuals move through a series of stages, or 'stages of change,' during PA adoption (Marcus et al., 1992; Marcus and Forsyth, 2009) and specific behavioral and cognitive processes occur as individuals move through each stage. Some of the behavioral processes include enlisting social support, rewarding oneself, committing oneself, and reminding oneself (Lewis et al., 2002). The five stages of change are (1) precontemplation, (2) contemplation, (3) preparation, (4) adoption, and (5) maintenance. According to the TTM, interventions should be tailored to the individual depending on their current stage of change, which can be identified with the following questions:

1. Are you currently accumulating at least 150 min of moderate intensity PA each week?
2. Have you been regularly physically active over the last 6 months?
3. Are you doing any PA?
4. Have you made any actions and/or concrete plans in increasing your PA?
5. Do you plan on becoming more physically active over the next 6 months?

Once you have answers to the above questions, you can better develop a plan of action specific to each client and tailored to their current stage or readiness.

Health Belief Model

The health belief model (HBM) is a conceptual framework outlining an individual's based on his/her health beliefs (Rosenstock, 1974). The model states that as individuals take greater investment in their personal health, they are more likely to make relevant and meaningful behavior changes. The four main components of the HBM are:

1. perception of susceptibility for the identified health threat;
2. perception of the severity of the identified health threat;
3. perception of the benefits from taking action to reduce the identified health threat; and
4. perception of barriers and/or costs of taking action to reduce the identified health threat.

According to the HBM, an individual examines the negative aspects of particular health action and/or behavior and weighs those 'costs' with the benefits of the health action. If benefits outweigh the costs, then a healthy action is more likely. This can also be considered as an equation in which (1) (susceptibility + seriousness) = perceived threat, (2) (benefits + barriers) = outcome expectation, and (3) (threat + expectations) = likelihood of action.

The HBM can be especially relevant when working with individuals and groups who are at higher risk for sedentary related chronic diseases such as cardiovascular disease, diabetes, arthritis, high blood pressure, dyslipidemia, etc.

Social and Cultural Principles in Promoting Physical Activity

Self-Efficacy/Social Cognitive Theory: PA self-efficacy is a term used to describe individuals' specific self-confidence in their ability to engage in PA. More broadly, self-efficacy is part of the Social Cognitive Theory (SCT) (Bandura, 1986) and postulates that the more confident one feels in their capabilities and skills to succeed, the more likely they will engage in that behavior (Bandura, 1977). SCT provides a theoretical framework for understanding PA adoption (McAuley and Blissmer, 2000) and emphasizes reciprocal determinism, or the interaction between individuals and their environments. SCT identifies three main factors that influence behavior and behavioral choices: (1) the environment (e.g., neighborhood, proximity to gym), (2) individual personality characteristics and/or experience (including cognitions), and (3) behavioral factors. Behavior is the product of the interplay between these three factors. In other words, the environment can influence individuals and groups, but individuals and groups can also influence their environments, and in turn, govern their own behaviors. Intervention studies indicate that self-efficacy is like an important component of PA behavior change across a variety of populations (Lewis et al., 2002; White et al., 2011; Haas, 2011). Self-efficacy is a product of four sources of information: (1) enactive mastery experience, (2) vicarious experience, (3) verbal persuasion, and (4) physiological or affective states. Each of these sources can be used individually or collectively to increase self-efficacy (Bandura, 1977). Assessing PA self-efficacy enables the practitioner to tailor feedback and encouragement to each client. To conduct the assessment, ask individuals how confident they are in their ability to regularly engage in PA. Using a PA self-efficacy scale of 1 (not confident) to 5 (very confident), individuals can be categorized as low or high PA self-efficacy, then tailored feedback can be offered, particularly for those with low confidence.

Social Support

Social support research indicates that when support comes from family and friends it can be an important component for exercise adherence (Anderson et al., 2006). Social support refers to anything a friend or family member does to help increase the individual's exercise level. Examples of social support strategies include encouraging exercise, exercising with the individual, watching the individual's children so he or she can exercise, or providing monetary support for attending exercise facilities. In the exercise setting, social support is often achieved via active participation, which creates a health-related win–win situation for both persons. The odds of success in PA are increased when goals are shared with friends and family, which also creates a greater sense of obligation and ownership for the goal-setter. However, the amount and type of social support that is most helpful varies between individuals.

Policy and Environmental Concepts and Principles in Promoting PA

The Social Ecological Model (SEM) is a comprehensive approach to change that integrates intra- and interpersonal factors including community and organizational factors, institutional factors, environmental factors, and public policies (**Figure 1**). All levels of the SEM are equally important, and all can influence individual behavior (Bronfenbrenner, 2009).

Many different versions of the SEM exist in regards to PA, each including a microsystem (personal interactions between family members, work groups, etc.), mesosystem (the physical setting for family, school, and work), and exosystem (the larger social influences of economics, policies, culture, and politics) (Bronfenbrenner, 2009). The SEM is specific to the promotion of health behaviors and focuses on assumptions related to influences of the physical and social environments, multidimensional environments, interactions between individuals, families, and communities, and how individuals influence their surroundings (Stokols et al., 2003).

Figure 1 Socioecologic model and the promotion of physical activity.

More recent attention has been on the significant role the environment plays on PA and health behaviors. Fields of transportation, urban planning, school zoning, access to facilities and programs, and supporting social environments that encourage activity may all influence PA behavior (Davison and Lawson, 2006; Heath et al., 2006). Empirical evidence suggests that the social, physical, and policy environments influence PA participation, and the SEM provides the framework to better understanding these factors and barriers. The SEM helps to identify opportunities to promote participation in PA by recognizing the multiple variables that may influence an individual's choices.

Building Community Capacity to Promote Physical Activity

Capacity building is seen as a critical element of health promotion and can be used to address a variety of population-based health risks including PIA (Canadian Cancer Society, 2013). As a community development tool, capacity building occurs on, and creates change at, three separate but related levels – individual, organizational, and social. Capacity building strives to create an increase in the ability of individuals and groups to positively impact the health and well-being of their communities, and to sustain this impact indefinitely. PA occurs in individuals and communities, and when performed at sufficient levels, can bring considerable health benefits, including reduced morbidity and mortality (PAGAC, 2008). Although the prevalence of PA is difficult to measure precisely, it is agreed that considerably less than 50% of the U.S. adult population is regularly active (Carlson et al., 2010) and no more than 35% of students in grades 9–12 meet recommended levels of PA (YRBSS, 2007). Additionally, the body of evidence on community-based PA interventions has grown (CDC, 2001; Kahn et al., 2002). Using strategies based on the socio-ecological perspective, effective PA promotion can occur for individuals, groups, and communities.

Essentials of Community Organization and Community Development

Community-wide campaigns are intended to be sustained efforts with ongoing high visibility. They can be large or small in scope, involve multiple partnerships, and should use various forms of media. A brand or tag line can be especially helpful, as was "VERB, It's What You Do," the CDC's successful youth PA campaign (CDC, 2010). Capacity building for a community typically involves health fairs, community events, policy change, risk factor screening and education at worksites and schools. Additionally, messages can be tailored to fit specific target populations such as school children, worksites, retirees, etc. (Kahn et al., 2002). There are a number of key elements necessary to deliver a successful community wide campaign, but regardless, all campaigns are resource intensive and require a large number of well-trained staff. The initial step in any successful campaign is to conduct the appropriate formative research to develop an effective theme and messaging. Without

a complete and thorough understanding of the community's needs and interests, it is unlikely any campaign can succeed. Concomitant with identifying the community needs and interests is gaining the community's buy-in to the process and intended outcome(s). This may require a considerable amount of time and work, and should include gaining the support of key community leaders, such as the mayor, work-shift leaders, school principals, and others that can positively influence attitudes in the community.

Effective Partnering and Coalition Building

A coalition is an alliance of individuals and organizations that come together to address a specific problem or issue. Goals that focus on system-wide changes and collaborations and require a variety of expertise are particularly well suited for coalitions (Rabinowitz, 2013). Stakeholders invest in a coalition when there are achievable goals and objectives to benefit from, yet unable to achieve on their own. Some inherent coalition benefits include expanding business networks, improving access to contacts, strengthening political position, and increasing access to funding opportunities. For any coalition to be successful there needs to be clear expectations toward the goal, strong leadership, and adequate staffing. At the same time, barriers need to be overcome, including finding the right lead organization, competition between coalition groups, perceived cost–benefit factor, and agreement on a common goal (Cohen et al., 2002). To initiate a community coalition for PA, the recommended steps are grouped under Formation, Management, and Evaluation. Formation includes a diverse group of stakeholders, ample front-end time to prepare, establishing a shared vision, and conducting a needs assessment. The final step of Formation is to create a data-driven plan, using an established strategy like Specific, Measurable, Appropriate, Realistic, and Time specific, and based almost exclusively on the needs assessment. The Management step requires a shared approach to responsibility, effective lines of communication, and a means and schedule for monitoring progress. This last piece should include the flexibility to reassess, revise, and recommit any and all aspects of the goal or plan, but should be based on the available data, not on anecdote or intuition. During Evaluation there is a continuous need to assess the coalition's efforts and to share the lessons learned along the way.

Program Evaluation Tools to Improve Programs

Program evaluation is the final step in determining the outcomes of any organizational efforts. Evaluations can be conducted using many different tools, but regardless, it is best to establish the evaluation plan prior to implementing any aspect of the proposed program, as post-hoc evaluations plans tend to be biased. A vast array of tools exists for evaluating community-based PA programs: The Framework for Program Evaluation in Public Health (CDC, MMWR, 1999), the Physical Activity Evaluation Handbook (USDHHS, 2002), and the Strengths, Weaknesses, Opportunities, and Threats (SWOT) analysis (Fine, 2009) are some of the more common. The Community Toolbox (The Community Toolbox, 2013) is an outstanding resource providing comprehensive information for each stage of community health promotion initiatives, including a How-to guide, Toolkits for completing tasks, a Troubleshooting section, and complete information on evidence-based practices.

Evidence-Based Community-Level Strategies for Promoting Physical Activity

In light of the scientific guidelines issued by various international bodies, national centers/institutes, and professional organizations, and the recent international evidence review documenting that regular PA protects against major NCDs (Lee et al., 2012), there appears to be significant health benefits accrued among whole communities by engaging in regular PA (Global Advocacy Council for PA, 2010).

As recently described by Heath et al., 2012, interventions designed to increase PA among whole populations are now much more prominent among public health and health system interventions (Kahn et al., 2005; Heath et al., 2006, 2012). Since PA behaviors are understood by factors that operate concurrently at multiple levels of influence (personal, social/cultural, environmental levels), approaches that operate across various community sectors appear to be the most successful in increasing PA among community residents (Kohl et al., 2012). Therefore health service and public health agencies need to partner with community organizations, including schools, businesses, policy, advocacy, nutrition, recreation, planning, and transport agencies to effectively collaborate, cooperate, coordinate, and communicate promotional efforts to increase PA (Heath et al., 2012).

For convenience, effective community-based PA intervention strategies are presented using the domains established by the Guide to Community Preventive Services (Kahn et al., 2002). These domains conveniently capture the majority of PA intervention strategies delivered throughout the world and consist of descriptors that are also found in other international PA recommendation documents (Heath et al., 2012; **Table 3**).

Physical Activity Interventions that Work

Campaigns and Informational Approaches

Community-wide campaigns are recommended within the campaigns and informational approaches domain

Table 3 Community-based PA intervention domains

1. *Campaigns and Informational approaches* to promoting PA – these are strategies aimed at changing knowledge, atti1tudes, and behavior about the benefits of and opportunities for PA within a community.
2. *Behavioral and social approaches* are aimed at teaching people the behavioral management skills that are necessary for successful adoption and maintenance of behavior change, and working through or creating organizational and social environments that facilitate and enhance behavioral change.
3. *Environmental and policy approaches* that are aimed at structuring the physical and organizational environments so that people have accessible, safe, attractive, and convenient places to be physically active.

(Table 4). These campaigns represent large-scale, high-intensity, high-visibility programming using various media to raise program awareness, disseminate targeted/segmented health messages, and reinforce behavior change. This strategy often employs multicomponent, multisector, and multisite interventions, and are representative of PA promotion efforts directed primarily toward populations living in communities within middle to high income countries (Heath et al., 2012). Mass media campaigns are another intervention strategy that produce PA behavior changes in selected populations, especially when they are linked to specific community programming. An emerging PA intervention strategy which has been employed among Latin American communities is an informational approach using (1) delivery of short PA-related educational and motivational messages, (2) delivered by a health educator/communicator, and (3) to a specific population at key community sites (Table 4). Point-of-decision prompts is an effective single-component informational strategy for promoting PA. This consists of signage designed to remind and motivate people to make acute healthy choices, such as using the stairs instead of the elevator (Table 4).

Behavioral and Social Approaches

The intervention domain of behavioral and social approaches to promoting PA encompasses a number of strategies that are site- and population-specific. Individually-adapted health behavior change programs represent a broad array of interventions that are multi-component approaches, with the goal of having participants incorporate PA into their daily routines (Kahn et al., 2002; Heath et al., 2012). The components of this strategy include goal setting, social support, behavioral reinforcement through self-reward, structured problem solving, and relapse prevention. These interventions are often delivered by email, internet, mail, and/or telephone. Individually-focused interventions usually consist of an assessment of a participant's PA level and readiness to change, a tailored activity plan, and navigation to community interventions by a centralized health provider or promoter. This approach, which focuses on lifestyle PA, has been shown to be cost-effective when compared to supervised PA programs (Roux et al., 2008). Another strategy within the domain of behavioral and social approaches is social support interventions in community settings, which capitalizes on social networks to reinforce PA behavior. Such a strategy can include creating buddy systems, contracting, and forming PA support groups. Community settings where such social support interventions can be carried out include worksites, community centers, health facilities, and parks and recreational facilities. Healthcare provider-based assessment and counseling for PA has undergone systematic review by several different groups (Heath et al., 2012) and still lacks sufficient evidence to be recommended as single component intervention. However, some investigators have demonstrated improved success with this strategy when it is integrated into existing community efforts and has emerged as a promising practice for PA promotion (Patrick et al., 2009). Others have found that the evidence for health-care provider assessment and counseling of patients for the promotion of PA is mixed. Brief stand-alone counseling by providers is not efficacious, but office-based screening and advice followed by telephone or community support for PA is effective in sustaining more long-term PA behavior improvement among patients (van Sluijs et al., 2005). Thus, healthcare provider delivery models that emphasize coordination with clinical and community resources may be the most optimal in promoting PA among healthcare patients (Pavey et al., 2011). An emerging behavioral and social approach to promoting PA is the convening of PA classes in community/public settings for community residents, with no cost to the participants. These programs provide social support, create opportunity where recreational deficits exist, and are relevant for underserved populations that are less likely to achieve PA recommendations. Such populations include women, older adults, and people with limited income. Since participation in such programs usually do not incur payment by the participating public, these strategies may also contribute to reducing social and health disparities (Heath et al., 2012).

Recommended strategies within the behavioral and social domain are school-based interventions such as school-based physical education (PE). These intervention strategies provide great potential to increase levels of PA among children and youth since in many countries PE is mandatory. This increases the likelihood of the least active children participating in some level of regular PA (Heath et al., 2012). School-based interventions also include programs delivered during school time as well as afterschool where core components for the effectiveness of such programs include: increased PA sessions, improved quality of PE classes, increased PA during recess and other times, teacher capacity building and training, changes in PE curricula; provision of equipment and materials; and adjustment of the interventions to specific target populations

(Heath et al., 2012). School-based interventions have been evaluated across outcomes such as PA level, fitness, obesity, other cardiovascular risk factors, and measures of well-being (Heath et al., 2012).

Policy and Environmental Approaches

An effective set of intervention strategies representing the policy and environmental domain is the creation of or enhanced access to places for PA combined with informational outreach activities (Heath et al., 2012). These interventions often consist of creating/enhancing existing walking/biking trails or exercise facilities, and increasing access to existing facilities by reducing structural and environmental barriers (e.g., increasing safety, enhancing affordability) (Heath et al., 2006, 2012; **Table 4**).

Community-scale urban design and land-use policies and practices commonly strive to create more livable communities and have been shown to be effective in promoting PA at the community level (Heath et al., 2006, 2012). These types of interventions use policy instruments such as zoning regulations and building codes, and environmental changes brought about by government policies or developers' practices. The latter includes policies encouraging transit-oriented development, and policies addressing street layouts, density of development, increased store location, jobs and schools that can be walked to (Heath et al., 2012). The NICE review addressing the promotion of PA through built or natural environments provides further evidence in support of this strategy outside of North America (NIHCE, 2008). Given the diversity of countries and populations included in these bodies of evidence, these results should be applicable to diverse settings and populations, provided appropriate attention is paid to adapting the intervention to the target population.

Street-scale urban design and land-use policies to increase PA use policy instruments and practices to support PA in small geographic areas, generally limited to a few blocks. These policies and practices include improved street lighting or infrastructure projects that increase the ease and safety of street crossing, ensure sidewalk continuity, introduce or enhance traffic calming, or enhance the aesthetics of the street area, such as landscaping (Heath et al., 2012). These interventions are designed to enhance the urban environment and/or to increase PA by redesigning streets and sidewalks, creating bike lanes/ways, and improving the perceived environment (Heath et al., 2012). These interventions are internationally representative and cross multiple countries (Heath et al., 2012).

Transportation and travel policies and practices that promote PA include interventions that strive to improve pedestrian, transit and light rail access, increase pedestrian and cyclist activity and safety, reduce car use, and improve air quality (de Nezelle et al., 2011; Heath et al., 2012).

A potentially effective intervention strategy is the use of community-wide policies and planning combined with multicomponent efforts at the community level to promote PA (Reis et al., 2010; Heath et al., 2012). These community action plans and policies are designed to reduce environmental and structural barriers that directly impact PA behaviors and are promoted through media campaigns and incentives at various levels (e.g., individual, corporate, local, and regional) (Reis et al., 2010; Heath et al., 2012).

Summary

As the aforementioned international perspective on PA intervention shows, there are a number of evidence-based approaches that demonstrate an acceptable level of effectiveness in increasing PA across different ages, social groups, and countries. Similarly there are several promising and/or emerging interventions specifically from middle-income countries that deserve attention and more rigorous evaluation. Among children and youth, there is enormous potential to increase PA through school-based initiatives. For the whole population, and particularly for adults, there is much to be gained through developing policies and environmental supports, particularly through partnerships with the sectors of transport and urban planning that can increase opportunities for PA within communities. Interventions are likely to be more effective, to the extent that they can address the determinants of PA at multiple levels. Ideally, PA initiatives should apply the relevant conceptual models and address the determinants at individual, behavioral, social, and environmental and policy levels tailored to specific populations across and within countries.

Abstract

Despite substantial differences, at different times in their development the physical sciences have provided a pattern for scientific work in the social and behavioral sciences as well as important theoretical resources and methods of working, and novel forms of social organization. This brief history pays particular attention to the changing social organization of the physical sciences, the development of sociological study of their activities, and the relations that were established with the social and behavioral sciences in the nineteenth century, when present disciplines in these subjects were beginning to form.

Origins of the Physical Sciences

Questions about the historical origins of the sciences have often rested on understandings of the nature of science and their relations to social systems, and answers to them have changed quite radically over time. From the early twentieth century to the 1960s, scholars emphasizing theory and rationalism typically argued for ancient Greek origins and often focused on the geometric (kinematic) models of planetary motion characteristic of Ptolemaic astronomy. More recently scholars have drawn attention to the work of Sumerian and Babylonian astronomers, whose records dating from the seventh century BCE show the use of predictive linear arithmetical sequences to calculate the periodicity of the day and planetary motions, and who related astronomical observations to astrological divination without closely linking astronomy and cosmology as the Greeks did. Babylonian influences on Indian and Greek astronomy had long been recognized. It is now clear that unjustifiably strict dichotomies between theoretical and practical, and rationalist and religious interests had been central to the argument that Babylonian contributions were merely practical, religiously motivated, and prescientific (Rochberg, 2002). Building on specialist studies of the regions concerned, comparative approaches have also begun to bring new complexity to our understanding of the pursuit of astronomy and mathematics in ancient China, as well as Greece and Mesopotamia. Where social and cultural factors are invoked to explain differences, most often they are mentioned in connection with the contrast between a relatively centralized and state-funded endeavor in China (leading to stability but also the potential for conservatism), and the need for philosophers to find fee-paying audiences in Greece – something that promoted an interest in novelty and a more free market competition of ideas (a competition that could also approach chaos and lead to discontinuities) (Lloyd, 2002). In broad outline, a contrast of this kind has been pervasive in studies of the sciences, reaching through to the Cold War. However, in the detailed examination of particular subjects in particular periods there are too many exceptions to ready-made generalizations about the relations between open or closed societies and science to allow those generalizations to stand without nuance and qualification: science has been pursued successfully under many different social systems.

While ancient societies surely offer precedents, and in the case of astronomy a continuous history of concern and development, some historians would date the physical sciences in their present form only to the nineteenth century, which saw the rise of modern experimental disciplines within research universities in Europe and the Americas. Yet the basic concepts and founding institutions in the physical sciences trace back to the scientific revolution. The rise of the sciences in Europe in the early modern period depended in part upon the assimilation of new writings from ancient Greece but also upon existing scholarly traditions (developed in close relations with religious and professional training), rising populations, the expansion of trading networks (and increasing pace of trade, together with the introduction of credit), and the development of seafaring navigation. It also occurred in a context of continual warfare and increasingly democratic societies (Jacob, 2007, reviewing Park and Daston, 2006). Multifactorial understandings of this nature stress the complexity of the social environment in the period in which the institutions of science were formed and have shown convincingly that, despite the fact that the Catholic Church forbade teaching of the Copernican system and that the early societies or academies initiated to cultivate the sciences were formed outside existing universities, new knowledge was far more importantly formed in dialog with religious and educational traditions than in opposition to them. While oppositional tropes and a stress on novelty do pepper some writings of the period, scholars have found they often obscure the nature of earlier contributions (the medieval period was more productively innovative than has often been thought), and it is also important to note that many figures involved, including notably Bacon and Newton, believed they were engaged in the rediscovery of truths long lost rather than the creation of something thoroughly new (Lindberg, 1990).

While structurally similar to Aristotelian understandings in some respects, a view of the world emerged that relied on and gave distinctive emphasis to understandings of the physical sciences that bridged the earth and the heavens, utilized new instruments like the telescope, microscope, and air pump (extending the senses and creating novel environments), pursued an empiricism most sharply represented in private experimental trials and public demonstrations, and could in some instances be closely related to mathematics. The mechanical or corpuscular hypothesis that became widely

shared offered a new assessment of the relations between nature and artifice, emphasizing the possibility of knowing nature in the way that human machines like the mechanical clocks that had been developed since the thirteenth century were known. Intellectual and social tensions between practical and theoretical knowledge and artisanal, commercial, and elite contributions to natural philosophy are abundantly visible in the founding of the early scientific academies and in the development of experimental practices (and such tensions are still felt). Natural philosophy would provide useful knowledge, and this was supposed to be less authoritarian and more open than the scholarly knowledge professed to a passive audience in universities. Yet the audience at Royal Society meetings was circumscribed, Boyle and others routinely neglected to mention the servants and workmen who assisted them in the production of complex experiments, and business interests might be thought to weigh against the credibility of philosophical engagement. Establishing mutually beneficial patronage relations was also important. While the relations of the Royal Society with the British crown were largely symbolic, the Royal Academy of Science in Paris established a hierarchy of salaried and nonsalaried positions. Although many natural philosophers worked primarily in a scholarly setting (like Galileo and Newton), the social norms that most thoroughly informed the new practices being developed were those of the gentleman, and the most common site for early laboratories was the gentleman's home. It was a largely private place (Shapin, 1988, 1989).

Within the physical sciences there were tensions between diverse philosophical stances and methodological approaches, and these often relied upon quite different intellectual and material resources to develop novel claims. Both mathematical and experimental approaches were advanced, and authors such as Descartes, Hooke, and Boyle offered a variety of forms of mechanical philosophy. Traditions in natural magic and alchemy were also important for many participants, such as Boyle and Newton (again, recent scholarship has shown close relations between activities earlier scholars had thought opposed, such as chemistry and alchemy). Although communication of results through the journals founded for this purpose allowed a form of virtual witnessing and had the potential to distribute novel claims widely through the republic of letters, the rarity of some of the resources involved (such as particular forms of optical glass) as well as the necessity of advanced training or personal contact to impart particular techniques (like Newtonian fluxions) meant that diverse communities of practice developed. As a result the methods, aims, and findings of different natural philosophers were often contested, and the wide scope of the debates that took place in the period has provided fertile grounds for linking historical and sociological investigations.

In the early twentieth century, Robert Merton had built on Weber's study of the puritan ethic and capitalism to argue that rather than inhibiting science, English Puritanism had offered cultural values that supported the rise of the experimental sciences (Merton, 1938). He subsequently elaborated a form of sociology that investigated the ethos informing the organization of scientific activity, which he identified in the four values of communism, universalism, disinterestedness, and organized skepticism (*see* Strong Program, Sociology of). Merton paid close attention to those circumstances in which tensions between ethos and institution arose, but did not discuss the content of science in any detail (Merton, 1973[1942]). In contrast, the 'strong program' in the sociology of knowledge that British sociologists articulated in the 1970s opened truth claims to social analysis, combating the assumption that only false beliefs (or the more general norms Merton had analyzed) need to be explained sociologically. Central tenets were that sociological study should be causal, impartial to the truth or falsity of claims, offer a symmetrical form of sociological understanding (giving the same kind of explanation for true and false beliefs), and be reflexive (Bloor, 1991[1976]). Central techniques were to analyze the interests of participants; study controversies, which often emerge around contested attempts to replicate experiments, because they expose the tacit dimensions of scientific work (Collins, 1985); and investigate contemporary laboratories anthropologically, something that led to a form of actor network analysis (Latour and Woolgar, 1979; Latour, 1987). While sociologists and anthropologists developed case studies of recent or current science (Collins notably studied the replication of a laser instrument, and research on gravity waves, while Traweek compared high energy laboratories in the United States and Japan (Traweek, 1988)), historians of early modern science have also drawn significantly on these approaches. Shapin and Schaffer's study of the debates between Boyle and Hobbes was particularly important, showing that diverse understandings of the relations between religion, the state, experimental philosophy, and the status of knowledge derived from the air pump were all at stake in accounts of specific facts; and describing material, literary, and social technologies in the production of knowledge (Shapin and Schaffer, 2011[1985]). Other influential work exploring historical episodes with importantly sociological aims include studies of the relations between instrument and interpretation in the debate around Newton's prism experiments and acceptance of his theory of light and color, and of patronage in Galileo's research and of his trial (Schaffer, 1989; Biagioli, 1993). While 'social constructivism' has sometimes proved controversial, forms of methodological relativism focused on recovering actors' understandings of their activity as a first step in analysis have been widely important in historical work. Perhaps the most general sociological issue underlying changing historiography of the period has been that of boundary work (the historically and situationally relative stipulation of demarcations between science and nonscience), understood across diverse periods. In many cases the sharp distinctions between sciences and other activities pointed to above have been found to reflect later perspectives, rather than contemporary concerns (Gieryn, 1983). One challenging argument has been that Boyle's understanding of mechanism and his gas law embody gendered perspectives, thereby closely relating gender studies to the substance of chemistry and not only the more commonly addressed question of participation in the physical sciences (Potter, 2001; Kovacs, 2012a,b).

Newtonianism over Time and Physics as One Discipline among Others

Patronage, institutional context, and audience have all been shown to play a formative role in the development and propagation of particular research fields, techniques, and knowledge

claims. The fortunes of Newton's work in different contexts illustrate this point, indicating the multifaceted nature of scientific work, and also just how radically understanding of its potential implications can change over time. His *Principia Mathematica* (1687) and *Opticks* (1704) offered rather different models for natural philosophers, the first of a mathematical physics that depended on sophisticated mathematics and needed advanced training to be understood (but also, with book 2 of highly practical pursuits – mechanics rather than astronomy); the second of a speculative experimental physics. In Britain, Newton's views and techniques were propagated in both universities and dissenting academies, and his fluxions were taught, rather then Leibniz's form of differential and integral calculus. Followers advanced Newton's views in philosophical discussions and sermons, where Protestantism was reinvented on the basis of the new sciences and Newton's mechanics might offer a model for good government. Desaguliers, the leading demonstrator and public lecturer at the Royal Society in the 1720s and 1730s applied Newton's mechanics to the practical work of draining mines and swamps, and his spectacular experimental demonstrations offered a form of Newtonianism accessible to less mathematically gifted audiences (Jacob, 1976; Stewart, 1992). In France, where Cartesian models were accepted, reading and propagating Newton relied on translating his language, reworking his mathematics into Leibnitzian form and transforming French cartography to critique existing measures and substitute new values for the length of a degree of arc at different latitudes, showing that the Earth bulged at the equator as Newton predicted. Voltaire and Maupertuis were particularly important in this process, and both had traveled to Britain. Maupertuis addressed a wide range of audiences from the academy to the salon, and studies of Émilie du Châtelet (the author of the first and still standard French translation of the *Principia*) have helped disclose the gendered nature of the spaces in which natural philosophy was pursued (Terrall, 1995, 2002).

Over time, and in success, Newton's work came to stand for quite different things. Similarly, as is best illustrated by the gradual transformation of electricity from being a property of amber to something created, stored, and sometimes tamed in electrical machines, Leyden Jars and lightning, the phenomena explored by the physical sciences were also being chased into diverse aspects of nature and integrated into quite different intellectual and disciplinary constellations. By the end of the eighteenth century, Coulomb had used Newtonian distance laws to mathematize electrostatics and Laplace had extended his mathematics analytically and shown the stability of the solar system; and Newton's work was now being invoked as an example of human rationalism and symbol of the Enlightenment, rather than as providing illustrations of God's active role in the universe. At the same time Galvani's research with frogs and Volta's discovery of the battery were leading other researchers to link chemistry and physics in electrolysis, physics and biology in the study of the electric current in the nervous system, and later electricity and magnetism in a search for the interconversion of different forces that had distinctly romantic aims (Heilbron, 1999). In this period chemistry was the most important linking discipline, and Newtonian models were clearly regarded as limited. For Faraday, gravitation was a force apart that might be brought into a continuum with chemical, electrical, and magnetic forces propagating over time through a medium, rather than instantaneously at a distance. Over time his work helped found field theory, and a widespread concern with conversion processes contributed to what became energy physics; significant cultural and religious dimensions played into its development, and Smith has described a 'spiral of credibility' in the process of addressing wider audiences that helped propagate particular views beyond their origins in small groups of researchers (Smith and Wise, 1989; Smith, 1998).

Faraday both acted as a consultant for industry groups and addressed elite audiences who were intellectually and socially interested in natural philosophy in his Friday evening lectures at the Royal Institution (founded in 1799, initially to bring science to the lower classes). In contrast to his contemporary rival Sturgeon, who put electrical machines on show to model the world and stress his own role as a skilled maker, Faraday worked hard to yield simple experiments that would render natural laws visible to others: the experimenter must show he is a reliable spokesman for nature while representing nature as speaking for herself (Morus, 1998). Faraday's laboratory was a private place known to few, a place of research and not pedagogy. It is important to note that this was also the case in universities, where professors demonstrated phenomena in lectures before students who never entered the laboratory. This changed first in chemical teaching from the late 1820s through the work of Thomas Thomson in Glasgow and Justus Liebig in Giessen, and then in physics from the 1850s with the work of William Thomson (Lord Kelvin) in Glasgow (Gooday, 1990). It is highly significant that chemical industry and the development of electric telegraphy and the power industry around the steam engine provided markets for the kinds of skills that teaching laboratories could provide, and also that by working with their students these scientists created the first sustained schools of advanced research, generating collective work in the sciences of a kind and on a scale previously impossible. The thoroughgoing transformation of mathematical pedagogy from oral to written examinations in Cambridge achieved something similar in mathematical practice (Warwick, 2003). The characteristic scientific collective of the early modern period had been societies in the republic of letters (often looking for an audience); now it was taking the form of research schools in academic disciplines.

While teaching the skills required for advanced industrial society (or the teachers who could convey those skills) was one means for the physical sciences to address industry – and a need for this was highlighted in response to the widespread commercial competition expressed in the international exhibitions of the nineteenth century – figures like Kelvin and Maxwell also sought to determine and calibrate the units to be used in industry. This could be achieved in a variety of ways, and across many different fields of physics, from electrical standards important to the electric telegraphy and power industry through optical standards useful in research on heat and light sources, and standards of length that could be traced from international and national standards down to the gauges controlling machine tools and precision manufacturing. Determining metrological standards provided a second, highly

strategic means through which academic science could be rendered central to industry, and it was particularly significant for the disciplinary development of physics in the period in which physical laboratories first became widespread in the late nineteenth century (Schaffer, 1999). Following the example of the Physikalisch-Technische Reichsanstalt founded in Berlin in 1887, from the turn of the century leading industrial nations founded national standards laboratories to conduct and regulate such metrical work, while also undertaking related research (often in quite close contact with academic research) (Cahan, 1989). Later, military needs stimulated the creation of national laboratories to provide weapons and other critical resources.

A third activity relating the academic laboratory to industry has been the development of commercial instruments and products, where patenting and entrepreneurial activity in partnership with instrument makers or manufacturing firms has been characteristic. This too is notable in the nineteenth century (Kelvin's electrical instruments and relations with James White being a prime example), but it only received greater prominence for the academic sciences as a whole in the later twentieth century, when the distribution of patent profits to the university came to be regarded as an important source of funding, something that has been analyzed more fully in relation to biotechnology than the physical sciences. However, scholars have described the generic forms of instrumentation that often facilitated such innovation, and analyzed the ambiguous social place of the research technologists who have provided it, often working at the interstices of different academic disciplines and industry (Joerges and Shinn, 2001).

There are two important ways in which work in the physical and the social sciences were interrelated through the course of the nineteenth century, both being expressed in the academic foundations of the social sciences as these became disciplines at the turn of the century. The first has received widespread attention in studies of the rise of statistical thinking. In 1809 Gauss had analyzed the errors of astronomical observation, finding them to fit a distribution law; in the 1830s Quetelet moved from astronomy to social science, and applied Gauss's distribution to other phenomena like the chest measurements of Scots, and social statistics like birth, death, and crime rates. Looking for the laws of the average man he sought a social physics that would rest on the characteristics of the social body rather than individuals. It was only after statistics had been taken up in the emerging social sciences in this way that physicists like Maxwell and Boltzmann explored its application in the kinetic theory of gases (Porter, 1986; Stigler, 1986). Some physicists took the kinetic theory of gases to illustrate the increasing power of Newtonian mechanics. Yet many regarded physics to offer models rather than final truth, and by the turn of the century there was a widespread search for alternative foundations as well as antireductionist and phenomenological epistemologies. Mach, Pearson, and others popularized a vision of science as offering simply the most economical description of sensations. Alongside the statistical methods strongly advocated by Galton and Pearson, their epistemological modesty and emphasis on a common method across all forms of science was eagerly taken up by those advancing the social sciences as academic disciplines, especially in the United States (Porter, 1994).

Twentieth-Century Physics: Particles, Projects, and Panels

Physics became a laboratory discipline at the same time that physiology and experimental psychology did, and from the 1860s researchers like Helmholtz and Mach had linked each of these disciplines by combining studies of light, sound, and movement with research on the senses that perceived them. By 1900 X-rays, the electron and radioactivity were offering a vision that could penetrate surfaces, and relativity and quantum theory combined mathematical and experimental physics in an investigation of matter at extreme velocities and in atomic realms previously often thought inaccessible. For many, particle physics became the defining field of physics, and the disciplinary linkages that were closest to home were those with chemistry, through physical chemistry and then the role of the electron in quantum chemistry, and also with molecular biology, especially after the World War II. Such relations have been mediated by instruments such as X-ray diffraction apparatus and the electron microscope, as well as by theories such as quantum chemistry and the informational approach to biology. They also were mediated by people who linked diverse fields. In the case of molecular biology, transfers of instruments, techniques, and practitioners were facilitated by the funding choices of the Rockefeller Foundation, which sought to purge what they regarded as metaphysics from the study of life and encouraged physical approaches to biological research. However, despite hierarchical understandings of the disciplines, interchanges of this kind have also been pursued by antireductionists, and characterized by fruitful engagement between both approaches (Gavroglu and Simões, 2012; Kay, 1993, 2000).

Military needs stimulated closer relations between the physical sciences and the State throughout the Western world from World War I onward, and in World War II helped create a distinctive social form and new collective activity we can describe as project- or problem-oriented science. Different nations created interdisciplinary constellations directed toward the provision of clearly defined material goals – famously in the United States, radar and atomic bombs – bringing members of physical, chemical, engineering, and material science disciplines together with industrial corporations, all under military control. While researchers in industrial firms had earlier experienced somewhat similar constraints and advantages, the experience unsettled established hierarchies, created new funding expectations and involved scientists more extensively in managerial roles than that had been common previously. While some welcomed the changes to previous academic practice, others rued them, and the postwar political environment gave rise to new concerns. Studies of McCarthyism in the United States and of cybernetics in different nations have disclosed a distinctive tension between ideology and science that played out rather differently across Western and Soviet practice, with elements of an interpretation regarded as fundamental in one context sometimes being understood as ideologically distorted in the other (with these judgments also changing over time). They also have shown that, just as the proper social order of science has often been thought to rest preferentially in politically favored structures (whether they be democratic or communist), scientists in the

physical as well as the biological sciences have also found creative resources in social and political analogy. Examples include the elaboration of a 'democratic' bootstrapping form of nuclear physics developed with some success in the United States, and diverse treatments of the concept of information (Wang, 1999; Kaiser, 2002; Mindell et al., 2003).

Project science had major legacies for the conduct of physics after the World War II, with the continuation of weapons laboratories being accompanied by the development of accelerators that concentrated experimental work in a few major sites. In the development of the original atomic bombs, secrecy was not just a question of access but went along with compartmentalization as a managerial strategy; anthropological studies of the postwar weapons laboratory have examined the mix of political silence and technical passion that have sustained life on the other side of the security fence (Gusterson, 1996). When not connected with weapons work, particle physics is of little immediate economical value, so its results could be circulated freely. Yet it requires substantial investment. In the United States, the accelerators were initially understood to provide critical manpower, training the strategic elite required to produce future weaponry. Accordingly, as the Cold War priorities changed or were abandoned, particle physics went through boom and bust. In the boom period, groups of hundreds of researchers and technicians were formed to design, build, and run massive instruments and experiments lasting over decades, often coming together from widely dispersed home institutions to share beam time and floor space around increasingly elaborate detectors. Instruments and disciplinary organization alike were thoroughly reshaped in these extraordinary transformations of scale, and in the course of a career physicists now commonly move through a sharply calibrated hierarchy superimposed on differentiated but interrelated fields of work, transitioning from working as postdocs on defined task (yet needing to challenge expectations to win notice) to perhaps reach the status of project leaders who spend their time in bureaucratic work and searching for funds (Galison, 1997; Traweek, 1988).

In times of bust, physicists were forced to leave the field – sometimes for the financial sector – but they also saw the value of diversifying the training of their graduates. Retrospectively we can see that in at least one case this has helped overcome the costs of subdisciplinary specialization and balkanization. Following the decision to broaden the pedagogy offered prospective particle physicists in the 1970s, the work of savvy students who experienced teaching across both particle physics and cosmology allowed a unification of similar approaches to mass – the Brans–Dicke field in gravitational studies, and the Higgs field in particle physics – that had been published in the same journal while rarely being read by the same people (Kaiser, 2007). Although Europe was slow to gain an accelerator comparable to those developed in the United States, over time the political environment within which the European nuclear agency European Organization for Nuclear Research (CERN) was formed has allowed it to lead a more stable existence. Founded as an instrument of foreign policy by western European nations ready to devote national resources to the endeavour of promoting wider European cooperation, it is one of several examples of collectively international laboratories and organizations, most often achieved in fields with little direct strategic importance, such as space science, molecular biology, or nuclear fusion (Krige and Guzzetti, 1997). While the American physics community saw its hopes for a super conducting super collider dashed at the end of the Cold War, the work of two groups at the Large Hadron Collider at CERN in 2012 may have provided the first experimental evidence for the Higgs Boson, thereby demonstrating the success of the approaches to mass brought together in particle cosmology. Perhaps the best illustration of the unusual social achievement of work in particle physics is that this community has worked out ways for collaborations of thousands to author tightly reasoned papers representing work in common undertaken over many years (Galison, 2003). More than 5000 authors contributed to the two papers published by the Compact Muon Solenoid (CMS) and A Toroidal LHC Apparatus (ATLAS) collaborations at CERN, from several hundred home institutions.

Distributed authorship of a different kind illustrates the second novel social form that has been created by work in the physical sciences through the late twentieth century. Understanding the possibility of climate change over time has relied in part on laboratory studies as early as the 1860s that identified the fact that carbon dioxide was opaque to heat. Such research also relies in part on an understanding of the cycle of carbon through the atmosphere, oceans, and earth – and the potential for feedback loops to drive the climate to warm or cool – that was first stated in the 1890s, and in part on the recognition from the 1930s that emissions of carbon dioxide from industrial activity could be significant on a global scale. Different elements of this argument were offered by physicists, chemists, geologists, engineers, meteorologists, and oceanographers, a form of interdisciplinary collaboration that was developed piece by piece over many decades before it began to be widely persuasive, and which shows that discovery accounts provide a poor understanding of work in such complex fields (Weart, 2003). Demonstrating climate change has also relied upon the assessment of data on temperature, rainfall, barometric pressure, and the like, gathered daily by scientists working at observatories and laboratories to provide reliable weather predictions, with coverage of the globe gradually expanded over the course of the nineteenth and twentieth centuries, and then lifted into the atmosphere and space through the military environmentalism of the Cold War. The physical sciences have thus provided an infrastructure for agriculture, shipping, and air travel through meteorological observations. Always useful but long mundane, these now constitute a record of climate change that has been supplemented by such measures as tree growth and gas capture in ice to extend our understanding over much longer periods (Edwards, 2010). Yet the social and economic interests involved in building an argument that bears so closely on industry required more than interdisciplinary science and long-term climate records. The Intergovernmental Panel on Climate Change was formed by the World Meteorological Organization and the United Nations Environment Program in 1988 in order to provide governments with advice about the state of scientific understanding about climate change, its potential social and economic impacts, and possible response strategies. Recognizing the extent and character of the interests involved, its judgments are provided in reports that are regulated through a process of authorship and review that

includes government representatives as well as subject specialists. They represent the work required to build authority through meticulously distributed procedural authorship, and show that panel science is every bit as novel, challenging, and important a collective form of science as project science has proved to be.

Physicalism and Alternatives

Abstract

Physicalism is the doctrine that our world is fundamentally physical in nature. Substance dualism is an alternative doctrine, according to which there are certain fundamental, irreducible substances (objects) that are not physical – immaterial minds, entelechies, souls, or disembodied spirits. Property (or attribute) dualism, another alternative, maintains that there are fundamental properties that are not physical – spiritual properties or mental properties. Physicalism is a controversial doctrine, even among theorists who deny there is any supernatural realm. Various alternative doctrines to physicalism currently receive some currency, but none receives widespread acceptance. Whether our world is fundamentally physical remains a matter of dispute.

Physicalism

Physicalism is an ontological doctrine. It concerns what there is. There is no consensus about how, exactly, it should be formulated. The strongest formulation is that everything is physical. This formulation is sometimes weakened by restricting the quantifier word 'everything' to contingent existents, that is, to things that exist, but could have failed to exist. That allows, for instance, that there can be nonphysical Platonic universals, which are by hypothesis abstract necessary existents, provided that nothing in our world instantiates them. But many self-professed physicalists regard even this weaker formulation as too strong. They often do so, in part, on the grounds there are certain sorts of nonphysical, functional properties and kinds that have instances in our world, and that this should be compatible with physicalism properly formulated. There are other formulations of physicalism, which receive some currency, that are weaker than the blanket claim that literally everything is physical. Some appeal to supervenience, stating that the nonphysical must supervene on the physical, so that there can be no nonphysical difference without a physical difference (McLaughlin and Bennett, 2011). Some appeal instead to some asymmetric relation that the nonphysical is supposed to bear to the physical – realization, grounding, or constitution. No formulation of physicalism receives widespread acceptance as definitive (Stoljar, 2009). Before examining further formulations of physicalism, however, let us turn to the prior question of what counts as physical.

The Physical

Any doctrine of physicalism must presuppose some conception of what counts as physical. But there is no received view about what counts as physical (Montero, 2009).

Descartes held that the physical is extended in space and that the mental is not; he held the mental is in time, yet nonspatial. If, however, general relativity can be trusted, then nothing can be in time without being in space.

It will not do to say that something is physical if and only if it is in space-time. Many contemporary physicalists reject nominalism, the doctrine that there are no universals or abstract entities of any sort (Rodriguez-Pereyro, 2011). A physicalist can maintain that there are physical universals (e.g., universals cited in physical laws) and that they, as opposed to their instances, are not in space-time, and so that there are physical existents that are not in space-time. Also, physicalists might count mathematical entities such as pure sets (sets that contain only sets as members that contain only sets as members, and so on) as physical existents, despite the fact that pure sets are not in space-time, on the grounds that physics must posit such sets, given its essential use of classical mathematics. Furthermore, some physicists speculate that space-time is not fundamental; though they do not mean to deny, thereby, that what is fundamental is physical. Existing or occurring or obtaining in space-time is not conceptually necessary for being physical. Nor is it conceptually sufficient. Human thinking and feeling, for instance, occur in space-time (wherever the thinker or feeler is), but it does not follow from this that such mental events are physical events, or that the spatiotemporally located thinkers and feelers are physical objects.

Although in ordinary discourse the physical is often contrasted with the mental and the spiritual, it is inadequate to so characterize it. As concerns the spiritual, in a theological sense of 'spiritual' according to which the spiritual is supernatural (rather than mental), naturalism, roughly the view that the natural world is in principle understandable by scientific method and that nothing exists beyond the natural world, denies the existence of the spiritual since it denies that there is any supernatural realm (Papineau, 1993). But not all naturalists are physicalists. Some naturalists maintain, for instance, that although there is no supernatural realm and the world is understandable by scientific method, consciousness exists, is not physical, and moreover fails to be dependent on the physical in the way that nonphysical phenomena must be for physicalism to be true (Chalmers, 1996).

Physicality cannot be adequately characterized by contrast to the mental either. Thus, it will not do to say that something is physical just in case it is not mental. Intuitionists in mathematics maintain that mathematical entities and properties are mental constructs (Lemhoff, 2013), while mathematical Platonists deny that maintaining instead that mathematical entities and properties are mind-independent (Linnebo, 2013). Platonism in mathematics is not thereby committed to the view that mathematical entities and properties are physical.

Moreover, the stipulation that something is physical just in case it is not mental excludes a position that some physicalists want to hold, namely, there are mental phenomena, but that everything that is mental is physical. It also excludes idealism, the alternative to physicalism according to which everything, including the physical, reduces to the mental (Robinson, 2009). And it excludes other alternatives to physicalism as well. Proto-panpsychism is the doctrine that everything concrete (everything in space-time) has (yet to be discovered) protomental properties that are themselves neither mental nor physical properties, but that, in combination with physical properties, constitute mental properties, so that having a mental property just consists in having a combination of physical and protomental properties (Nagel, 1979; Seager, 2009). According to neutral monism, yet another alterative to physicalism, both mental and physical properties are ultimately to be explained in terms of neutral properties that are neither mental (nor protomental) nor physical (Stubenberg, 2013). The stipulation that something is physical just in case it is not mental would thus end the debate between physicalists, idealists, proto-panpsychists, and neural monists before it gets interesting. None of these alternatives to physicalism need be true for this objection to the characterization of physicality in question to stand. If any of these alternatives is even just conceptually coherent (i.e., not a priori false), then it is not a conceptual truth that something is physical just in case it is not mental.

One approach to characterizing physicality that has some currency appeals to exemplars of ordinary physical or material objects (e.g., rocks), and characterizes physical properties and relations (which on some views are universals) as follows: a property or relation is a physical property or relation just in case a complete account of the intrinsic nature of such physical objects and their microconstituents would have to appeal to it (Jackson, 1998). This proposal is inadequate. It too ends the physicalist's conversation with idealists, neutral monists, and proto-panpsychists before it gets interesting. Also, panpsychism is typically taken to be the view that every concrete object, no matter at what scale, has mental properties, that mental properties are not physical properties, and that mental properties are required to give a complete account of the intrinsic nature of exemplars of ordinary physical objects and their microconstituents (Nagel, 1979; Seager, 2009). If panpsychism is even just conceptually coherent, then figuring in a complete account of such physical objects and their microconstituents does not conceptually suffice for a property or relation's being physical. (It should be mentioned that at least one panpsychist employs the notion of physicality in question, but drops the claim that mental properties are not physical properties, and so maintains that panpsychism is a version of physicalism (Strawson, 2008). But the vast majority of physicalists would take this version of panpsychism, according to which certain mental properties are fundamental properties, to be an alternative to physicalism, a kind of property or attribute dualism (dualism all the way up and down the micro–macro scale), rather than a version of physicalism.)

A currently leading approach to characterizing the notion of physicality relevant to physicalism appeals to the explicit posits of physics. This appeal is made, in part, because, unlike any of the other sciences, physics aims to be a closed theory in the following sense: it aims to be a theory such that every caused state or event within its domain is such that there is a state or event within its domain that determines its objective probability (Davidson, 1970; Yablo, 1992). If causal determinism is true, that objective probability will be one; if causal indeterminism is true, it will be less than one.

Any approach that ties the notion of physicality to the posits of physics faces 'Hempel's dilemma' (Hempel, 1969; see also Crane and Mellor, 1990). If by 'physics' is meant current physics, then there is a problem if physicalism is characterized in terms of this notion of physicality, namely that current physics is likely false. If, on the other hand, by 'physics' is meant the ideally completed physics that is in fact true of our world, then to characterize the doctrine of physicalism in terms of this notion of physicality, the objection goes, would render the doctrine too obscure to be a subject of rational assessment, for there is no telling now what an ideally completed physics will have to posit.

Although current physics is enormously successful, it no doubt contains errors, and is by no means the final theory of physics; there is at present no adequate quantum theory of gravity, for instance. The first horn of the dilemma seems thus best avoided. What, then, of the second horn?

The problem raised by the second horn is not just that there is no telling (if there is indeed no telling) what an ideally completed physics will have to posit, and so that this notion of physicality renders physicalism too obscure to be a subject of rational debate. It is also the case that there is reason to deny that being posited by an ideally completed physics is a conceptually sufficient condition for being physical in the sense relevant to physicalism. Consider a far out possibility, but a possibility nonetheless. Suppose that it turns out that the physics true of our world is a Cartesian-like physics in that it posits nonspatial, but temporal minds that directly causally influence brains. Although that is incompatible with general relativity and it seems, moreover, preposterous to think that current physics has gone that badly wrong, it is nevertheless not a priori false that the physics that is in fact true of our world is such a Cartesian-like physics. Cartesian physics was not refuted by an a priori proof. It may be preposterous to think that the true, complete physics will be such a Cartesian-like physics, but it is not true by definition that it is not. Suppose, then, that the actual world contains Cartesian minds, substances that are temporal but not extended in space, and that occupy intrinsic, conscious states that exert a fundamental causal influence on the motions of particles in the brains of human beings, and, thereby, a causal influence on the behavior of human beings. Were that so, then the true, complete physics would be a Cartesian-like physics in that it would posit Cartesian minds. The reason is that mechanics, the theory of motion, is a central branch of physics. A true, complete physics would thus include a true, complete mechanics. A true, complete mechanics would take into account all of the fundamental causes of motion. Should states of a Cartesian mind be among those fundamental causes of motion, then a completed mechanics would posit them, and so physics would posit them. In one sense of 'physical', they would thereby count as physical. But that sense of 'physical' is not the one physicalists have in mind. Physicalists do not want to say that were that to turn out to be the

case, then such Cartesian minds are physical. Rather, they would say that were that to turn out to be the case, then physicalism is false since Descartes's substance dualism is true. It thus fails to capture the notion of physicality that typical physicalists are aiming for to say that something is physical if it would be posited by the ideally completed physics true of our world. That does not conceptually suffice for being physical in the sense that they have in mind. What, then, is that sense?
